Abstract

The standard view of adaptation to larval crowding in fruitflies, built on results from 25 years of multiple experimental evolution studies on *Drosophila melanogaster*, was that enhanced competitive ability evolves primarily through increased larval feeding and foraging rate, and increased larval tolerance to nitrogenous wastes, at the cost of efficiency of food conversion to biomass. These results were at odds from the predictions of classical K-selection theory, notably the expectation that selection at high density should result in the increase of efficiency of conversion of food to biomass, and were better interpreted through the lens of α-selection. We show here that populations of *D. ananassae* and *D. n. nasuta* subjected to extreme larval crowding evolve greater competitive ability and pre-adult survivorship at high density, primarily through a combination of reduced larval duration, faster attainment of minimum critical size for pupation, greater time efficiency of food conversion to biomass and increased pupation height, with a relatively small role of increased urea/ammonia tolerance, if at all. This is a very different suite of traits than that seen to evolve under similar selection in *D. melanogaster*, and seems to be closer to the expectations from the canonical theory of K-selection. We also discuss possible reasons for these differences in results across the three species. Overall, the results reinforce the view that our understanding of the evolution of competitive ability in fruitflies needs to be more nuanced than before, with an appreciation that there may be multiple evolutionary routes through which higher competitive ability can be attained.

Introduction

Adaptation to crowding leading to greater competitive ability, first conceptualized as *r*- and *K*-selection theory (MacArthur and Wilson 1967), is an important phenomenon in ecology and evolution that was extensively studied in *Drosophila melanogaster* over the past three decades, using experimental evolution approaches (reviewed in Joshi 1997; Mueller 1997; Prasad and Joshi 2003). In the case of lifespan, fecundity, starvation resistance and dessication resistance, some of the other traits extensively examined via

experimental evolution in *D. melanogaster*, there were conflicting reports of differing patterns of correlated responses to selection between laboratories (Rose *et al.* 1996; Ackermann *et al.* 2001; Prasad and Joshi 2003) that led, in part, to a growing appreciation that evolution is often 'local' (Rose *et al.* 2005). In the case of adaptation to crowding, however, the pattern of correlated responses to selection was largely consistent over two separate selection experiments, involving *D. melanogaster* populations originating from different geographical sources (*r*- and *K*-populations: Mueller and Ayala 1981; UU and CU populations: Joshi and Mueller 1996), and the suite of traits through which the selected populations evolved greater competitive ability was very different from the canonical version of *r*- and *K*-selection theory that emphasized the centrality of increased food to biomass conversion efficiency as an adaptation to chronic crowding (Mueller 2009).

Results from the earlier selection studies on adaptation to crowding in *D. melanogaster* have been reviewed extensively (Joshi 1997; Mueller 1997; Joshi *et al.* 2001; Prasad and Joshi 2003; Dey *et al.* 2012) and, consequently, we will just summarize the major observed correlated responses of pre-adult traits to selection. Relative to the low density *r*-populations, the crowding adapted *K*-populations exhibited greater (i) pre-adult survivorship, when assayed at high larval density (Bierbaum *et al.* 1989), (ii) pre-adult competitive ability (Mueller 1988), (iii) larval feeding rate (Joshi and Mueller 1988), (iv) larval foraging path length (Sokolowski *et al.* 1997), (v) pupation height (Mueller and Sweet 1986; Joshi and Mueller 1993), and (vi) minimum food requirement for pupation (Mueller 1990). Pre-adult survivorship of the *r*- and *K*-populations did not differ significantly when assayed at low larval density (Bierbaum *et al.* 1989). Pre-adult development time in *K*-populations was lower than that of the *r*-populations at low (30 larvae per vial) and moderately high (160 larvae per vial) density, but greater at very high (320 larvae per vial) density (Bierbaum *et al.* 1989). The evolution of higher larval feeding rate and pupation height in crowding adapted populations was subsequently verified with a separate set of populations (*rK* and *r* × *rK* populations), by Guo *et al.* (1991).

Relative to the control UU populations, the larval crowding adapted CU populations exhibited greater (i) pre-adult survivorship, when assayed at high larval density (Mueller *et al.* 1993; Shiotsugu *et al.* 1997), (ii) larval feeding rate (Joshi and Mueller 1996), (iii) larval foraging path length (Sokolowski *et al.* 1997), (iv) minimum food requirement for pupation (Joshi and Mueller 1996), and (v) tolerance to nitrogenous wastes like urea (Shiotsugu *et al.* 1997; Borash *et al.* 1998) and ammonia (Borash *et al.* 1998). Pre-adult survivorship of the CU and UU populations did not differ significantly when assayed at low larval density (Mueller *et al.* 1993; Shiotsugu *et al.* 1997). CU pre-adult development time was similar to that of UU populations when assayed at low larval density, but lower than the UU populations when assayed at high larval density (Borash and Ho 2001).

Pupation height of the CU populations was greater than the UU controls during early generations of CU selection (Mueller *et al.* 1993), but did not differ significantly from the controls after about 60 generations of selection (Joshi and Mueller 1996); possible reasons for this are extensively discussed by Joshi *et al.* (2003). Urea and ammonia tolerance were not assayed on the *r*- and *K*-populations, whereas competitive ability was not assayed on the CU and UU populations.

The *K*-populations differed from the *r*-populations in experiencing higher larval as well as adult density and, moreover, were kept on an overlapping generation regime whereas the *r*-populations were kept on discrete generations (Mueller and Ayala 1981). The CU populations on the other hand differed from the UU controls only in larval density (Joshi and Mueller 1996). Given the congruence in the pre-adult traits that evolved in the CU and *K*-populations, it is likely that these traits represented an evolutionary response primarily to levels of larval crowding. Thus, the overall picture that emerged from these two studies was that long-term exposure to larval crowding in *Drosophila* selected for increased larval feeding and foraging activity, at the cost of efficiency at converting food to biomass, a greater tendency to pupate away from the food, and a higher tolerance to toxic levels of metabolic waste (Joshi and Mueller 1996). It makes sense that these traits would contribute to greater pre-adult survivorship in a crowded larval culture characterized by diminishing food levels, greater chance of pupal drowning on the increasingly mushy food surface, and a rapid buildup of levels of nitrogenous waste. This has been the canonical view of adaptations to crowding in *Drosophila* for the past 15 years or so (Mueller 1997; Joshi *et al.* 2001; Prasad and Joshi 2003; Mueller *et al.* 2007; Mueller 2009; Mueller and Cabral 2012).

The notion that faster feeding is a strong correlate of pre-adult competitive ability in *Drosophila* has a lot of support. Populations selected for faster feeding rate were also found to be better competitors (Burnet *et al.* 1977), and populations selected for rapid pre-adult development evolved both reduced feeding rate and reduced competitive ability (Prasad *et al.* 2001; Shakarad *et al.* 2005; Rajamani *et al.* 2006). Similarly, populations selected for increased parasitoid resistance evolved both reduced feeding rate and reduced competitive ability (Fellowes *et al.* 1998, 1999). The notion that there is a cost to faster feeding (Joshi and Mueller 1996) was supported by the rapid return of feeding rates to control levels when CU populations were maintained at moderate densities (Joshi *et al.* 2003). There is also evidence for a trade-off between urea/ammonia tolerance and larval feeding rate. Populations selected for greater urea and ammonia tolerance, respectively, also showed reduced larval feeding rate (Borash *et al.* 2000) and larval foraging path length (Mueller *et al.* 2005), and populations selected for greater urea tolerance did not show higher survivorship than controls at high larval density (Shiotsugu *et al.* 1997). In general, larval feeding rate and forgaing path length appear to be positively correlated (Joshi and Mueller 1988, 1996; Sokolowski

et al. 1997; Borash *et al.* 2000; Prasad *et al.* 2001; Mueller *et al.* 2005). Thus, the evolution of competitive ability in *Drosophila* seems to be the outcome of a balance between mutually antagonistic traits like increased larval feeding and forging behaviour (and perhaps pupation height), greater tolerance to nitrogenous wastes, and a reduced efficiency of conversion of food to biomass. Indeed, the CU populations exhibited a temporal polymorphism for two of these traits : offspring of early eclosing flies in a crowded culture showed higher feeding rates, whereas offspring of late eclosing flies showed greater urea/ammonia tolerance than controls (Borash *et al.* 1998).

Given that the above view of adaptation to larval crowding in *Drosophila* was built around studies on a single species (*D. melanogaster*), we wanted to investigate whether other species of *Drosophila* would also respond to larval crowding by evolving essentially the same set of traits. If the genetic architecture of traits relevant to fitness under larval crowding is reasonably conserved across congeners, then we should see a similar pattern of correlated responses to selection for adaptation to larval crowding in other *Drosophila* species. We report results from two selection experiments, on *D. ananassae* and *D. nasuta nasuta*, involving selection for adaptation to larval crowding. *D. ananassae* is ecologically and phylogenetically closer to *D. melanogaster* (*Sophophora* subgenus; *melanogaster* group; *melanogaster* subgroup), being a cosmopolitan human commensal and belonging to the *melanogaster* group, *ananassae* subgroup and *ananassae* species complex, whereas *D. n. nasuta* belongs to the *Drosophila* subgenus, *immigrans* group, *nasuta* subgroup and *frontal sheen* species complex, and is found primarily in orchards and open land. Thus, these two species form a good paired contrast to *D. melanogaster*, and have also been extensively used for diverse investigations of evolutionary genetic questions (reviewed in Ranganath and Aruna 2003; Singh 2010). Our results showed that selected populations of both *D. ananassae* and *D. n. nasuta* exhibited similar patterns of correlated responses to selection for adaptation to larval crowding, but that these populations evolved greater competitive ability through traits very different from those seen earlier in *D. melanogaster* populations subjected to similar selection.

Materials and methods

Experimental populations

This study used eight laboratory populations each of *D. ananassae* and *D. n. nasuta*. Four control *D. ananassae* populations (AB$_{1-4}$: Ananassae Baseline) were derived from a single population, initiated in May–June 2001 with about 300 wild-caught females from Bengaluru, India, and maintained as a single population on a 21-day discrete generation cycle for 34 generations (Sharmila Bharathi *et al.* 2003). The four AB populations were maintained on a 21-day discrete generation cycle at 25° $\pm$ 1 C, ∼90% relative humidity, constant

light and on cornmeal medium. Larval density was regulated at 60–80 larvae per vial (9 cm $\times$ 2.4 cm) with 6 mL food. Forty vials were set up per replicate population. Twelve days after egg collection, eclosed adults (1500–1800) from all 40 vials were collected into Plexiglas cages (25 $\times$ 20 $\times$ 15 cm^3) containing a Petridish (9 cm diameter) of food that was changed every alternate day, and a moistened ball of cotton. On day 18 after egg-collection, the flies were given food along with a generous smear of live yeast–acetic acid paste. On day 21 from the previous egg-collection, fresh food plates were put in to the cages and eggs were collected from them after 18 h to initiate the next generation.

From the AB populations, four populations (ACU$_{1-4}$: Ananassae Crowded as larvae and Uncrowded as adults) were derived, one each from each of AB$_{1-4}$, two generations after the AB populations were established. The ACU populations were selected for adaptation to larval crowding by subjecting them to a density of 550–600 eggs per vial with 1.5 mL of food. In initial generations the density was lower; the final densities were attained by generation 15 of ACU selection. The ACU populations were otherwise maintained the same as the AB controls, except that only 20 vials of eggs were collected for each generation (to keep the number of breeding adults similar to controls: 1500–1800), and the collection of eclosed adults in to the cages continued until day 18 from previous egg-collection, as eclosion in a crowded culture is staggered over several days.

Four control *D. n. nasuta* populations (NB$_{1-4}$: Nasuta Baseline) were derived after 24 generations as a single population on a 21 day discrete generation cycle, from a laboratory population established using about 70 females collected from orchards and domestic garbage dumps in different parts of Bengaluru, India, during October–November 2001 (Sharmila Bharathi *et al.* 2003). The four NB populations were maintained on a 21-day discrete generation cycle at 25° $\pm$ 1 C, ∼90% relative humidity, constant light and on cornmeal medium. The larval density was regulated at 60–80 larvae per vial (9 cm $\times$ 2.4 cm) with 6 mL food. Fifty-two vials were set up per replicate population to keep the number of breeding adults at about 1500–1800. Twelve days after egg collection, eclosed adults from all 40 vials per replicate population were collected into Plexiglas cages (25 $\times$ 20 $\times$ 15 cm^3) containing a Petridish of food that was changed every alternate day, and a moistened ball of cotton. On day 18 after egg collection, the flies were given food along with a generous smear of live yeast–acetic acid paste. On day 21 from the previous egg collection, fresh food plates were put in to cages and eggs were collected from them after 18 h to initiate the next generation.

From the NB populations, four populations (NCU$_{1-4}$: Nasuta Crowded as larvae and Uncrowded as adults) were derived, one each from each of NB$_{1-4}$, two generations after the NB populations were established. The NCU populations were selected for adaptation to larval crowding by subjecting them to a density of 350–400 eggs per vial with 2 mL of food. In initial generations the density was lower; the final

densities were attained by generation 15 of NCU selection. This difference from ACU in larval density is to compensate for the larger size at each stage of the *D. nasuta* larvae. The NCU populations were otherwise maintained in the same way as the NB controls, with similar adult population size, except that the collection of eclosed adults into the cages continued until day 18 from previous egg collection, and only 40 vials with eggs were set up.

Since each ACU or NCU population was derived from one control population, selected and control populations of each species bearing identical numerical subscripts are more related to each other than to other populations with which they share the selection regime. Therefore, control and selected populations with identical subscripts were treated as blocks, representing ancestry, in the statistical analyses.

Collection of flies for assays

All control and selected populations were maintained under common (control type) rearing conditions for one complete generation prior to assays, to eliminate nongenetic parental effects. The progeny of these flies, hereafter 'standardized flies', were then used for various assays. To obtain progeny for assays, standardized flies in cages were provided yeast–acetic acid paste on food for three days before egg collection. A fresh Petridish with food was then placed in the cages and the flies were allowed to lay eggs for ∼14 h, after which eggs were removed from the food with a moistened paintbrush and placed in vials for setting up the various assays. All assays were conducted at $25 \pm 1°C$ under constant light.

Pre-adult survivorship

After 42 generations of ACU selection, eggs laid by standardized flies were placed into vials at a density of either 70 or 600 per vial containing 1.5 mL of food. Eight such vials were set up for each replicate AB and ACU populations at each density in single-species culture. Eight such vials at each density were also set up in two-species cultures, in competition with a common competitor, a white-eyed mutant population of *D. melanogaster*, maintained for about 90 generations in the laboratory on a three week discrete generation cycle. The white-eyed population was derived from spontaneously occurring mutant individuals in the JB populations (Sheeba *et al.* 1998) in our laboratory. For the two-species cultures, eggs laid by standardized ACU, AB or white-eyed flies were collected and placed in vials at a density of either 70 (35 ACU or AB eggs and 35 eggs from the white-eyed mutant population) or 600 (300 ACU or AB eggs and 300 eggs from the white-eyed mutant population) per vial containing 1.5 mL food. Eight such vials were set up for each replicate AB and ACU population at each density. The number of flies eclosing in each vial was recorded and used for calculating pre-adult survivorship.

At generation 76 of NCU selection, an assay similar to that described above was set up using the NB and NCU populations and the white-eyed *D. melanogaster*. The only difference from the *D. ananassae* assay was that the low and high density treatments comprised of 70 or 350 eggs in vials with 2 mL of food.

Duration of pre-adult life-stages and pre-adult development time

After 53 generations of ACU selection, pre-adult development time was assayed at a high density of 600 eggs per vial with 1.5 mL of food. Eggs from standardized AB and ACU flies were dispensed into each vial using a moistened paintbrush. Eight such vials were set up per replicate population. After the pupae darkened, vials were checked for every 6 h and the number of eclosing flies recorded.

After 71 generations of ACU selection, pre-adult development time was assayed at a low density of 30 eggs per vial with 6 mL of food (an earlier study at generation 41 of ACU selection had shown that pre-adult development time did not differ significantly between low densities of 30 or 70 eggs per vial with 6 mL of food: data not shown). Eggs from standardized AB and ACU flies were dispensed into each vial using a moistened paintbrush. Ten vials were set up per replicate population. After the pupae darkened, the vials were monitored for eclosion at 2 h intervals, and the numbers of eclosing flies were recorded. As part of the same assay, the egg hatching time and duration of each larval instar and pupal stages were also determined. For assaying egg hatching time, 30 eggs from the standardized flies were arranged on a small agar cube in a food vial in six rows of five eggs each. Ten such vials were set up per population. Fifteen hours after egg laying, the vials were checked for any hatched eggs once every hour, till no eggs hatched for three consecutive hours. For assaying instar and pupal duration, eggs of approximately identical age were harvested over a 3 h period from the standardized flies and dispensed into vials with 6 mL of food at a density of 30 eggs per vial. Sixty such vials were set up per population. Forty-three hours after the midpoint of the 3 h egg laying period, four vials per population were removed from the incubators and immersed in hot water. The dead larvae were removed and kept in 70% ethanol for subsequent examination. Every 2 h this process was repeated till all larvae would have been well into the third instar. The larval instars were differentiated based on the number of 'teeth' in the larval mouth hooks. From these data, the number of larvae of each instar present in each two-hourly sample was determined, and the median time of each molt was obtained by interpolation. For pupal duration and pre-adult development time, 10 vials per population were set up with 30 eggs in 6 mL of food. After the first pupa was seen, the vials were screened every 2 h and any new pupae that had formed were marked on the vial with different coloured marker pens. Thereafter, the vials were monitored for eclosion and the number of eclosing males and females in each vial was determined every 2 h. These observations yielded data on egg to pupa and egg to adult development time, from which the pupal duration could be calculated.

After 84 generations of NCU selection, pre-adult development time was assayed at a high density of 350 eggs per vial

with 2 mL of food. Eggs from standardized NB and NCU flies were dispensed into each vial using a moistened paintbrush. Eight such vials were set up per population. After the pupae darkened, the vials were checked every 6 h and the number of eclosing flies were recorded.

After 62 generations of NCU selection, egg hatching time, larval instar duration, pupal duration and pre-adult development time of the NB and NCU populations were assayed exactly as described above for the ACU and AB populations.

Larval feeding rate

After 71 generations of ACU selection, the feeding rates of AB and ACU larvae were measured at physiologically equalized ages, based on the difference in AB and ACU development time. This was done by collecting eggs from the standardized ACU flies 5 h later than the AB flies. Thus, at the time of assay, ACU larvae were 58 h old, whereas AB larvae were 63 h old and, thus, approximately in the same relative stage of their larval development. Following Joshi and Mueller (1996), about a hundred eggs laid over a 4 h period and were collected from standardized flies and placed into two Petridishes with nonnutritive agar each for AB and ACU populations. Twenty-four hours later, 25 newly-hatched larvae were transferred from these agar Petridishes to a Petridish containing a thin layer of nonnutritive agar overlaid with 1.5 mL of 37.5% yeast suspension. Four such Petridishes were set up per population. The larvae were then allowed to feed for 58 (ACU) or 63 (AB) h, by which time they were in the early third instar. At this point, 20 larvae from each population were assayed for feeding rate, following the procedure of Joshi and Mueller (1996), by placing them individually in a small Petridish (5 cm diameter) containing a thin layer of agar overlaid with a thin layer of 10% yeast suspension. After allowing for a 15 s acclimation period, feeding rate was measured under a stereo zoom microscope as the number of cephalopharyngeal sclerite retractions in a 1 min period. Selected and control populations, matched by the subscripted indices, were assayed together with one larva from the selected population and one from the control population being assayed alternately. The same procedure was followed for assaying larval feeding rate of 20 larvae from each NCU and NB population, after 77 generations of NCU selection.

Larval foraging path length

Twenty early third instar larvae for each population were assayed for larval foraging path length. The collection of larvae for the assay was exactly same as described above for larval feeding rate assays. For assaying foraging path length, individual larvae were placed in a small Petridish (5 cm diameter) containing a thin layer of agar overlaid with a thin layer of 10% yeast suspension. After allowing for a 15 s acclimation period, the larvae were allowed to move around on the Petridish for 1 min. The path traversed by the larvae on the yeast surface was traced onto a transparency sheet and later measured with a thread and ruler. Selected and control populations matched by subscripted indices, were assayed together at generations 52 and 81 of ACU and NCU selection, respectively.

Pupation height

Eggs from standardized flies were collected and placed into vials with 6 mL of food at a density of 50 (ACU/AB) or 70 (NCU/NB) eggs per vial. Ten and eight such vials were set up per population for *D. ananassae* and *D. n. nasuta*, respectively. Once all pupae had formed, pupation height of each pupa was measured, following Joshi and Mueller (1993), as the distance between the surface of the food medium to the point between the anterior spiracles of the pupa. Any pupa on or touching the surface of the food was given a pupation height of zero. Assays were conducted at generations 39 and 34 of ACU and NCU selection, respectively.

Larval urea and ammonia tolerance

After 49 generations of ACU selection, eggs laid over a 4 h period by standardized flies were collected and exactly 30 eggs per 6 mL food were placed into vials at three concentrations each of urea (0, 14 and 18 g/L) or ammonia (0, 15 and 30 g/L NH_4Cl) in the food. These are values that allowed the detection of differences in urea/ammonia tolerance between selected and control populations in previous studies on *D. melanogaster* (Shiotsugu *et al.* 1997; Borash *et al.* 1998). Ten vials were set up per population at each concentration of either urea or ammonia, and the number of eclosing flies in each vial was recorded to calculate pre-adult survivorship. Both urea and ammonia were used as there is some confusion about which compound actually increases in concentration in crowded larval cultures, although it is likely that it is ammonia in the case of *D. melanogaster* (Botella *et al.* 1985; Borash *et al.* 1998). The NCU and NB populations were assayed in an identical manner after 76 generations of NCU selection, except that the egg-laying period was 12 h, and the concentrations used were 0, 9 and 11 g/L for urea and 0, 15 and 20 g/L for ammonia, as earlier studies had shown that *D. n. nasuta* larvae were more sensitive to urea and ammonia than their *D. ananassae* counterparts, and *D. n. nasuta* females are not as fecund as *D. ananassae* females (data not shown).

Minimum feeding time and dry weight after minimum feeding

These assays were conducted only on the ACU and AB populations. After 45 generations of ACU selection, critical minimum feeding time for pupation was assayed by setting up freshly-hatched larvae, from eggs laid by standardized flies, onto Petridishes with agar overlaid with 1.5 mL of 37.5%

yeast suspension, as described above for the feeding rate and foraging path length assays. Twenty-five larvae were placed in each Petridish, and 60 such Petridishes were set up per population. At 46, 49, 52 and 55 h after egg hatch, a total of 150 larvae per population per time point were removed from the yeast, gently washed with water to remove any yeast sticking to their bodies, and placed in 10 vials containing 5 mL of nonnutritive agar, at a density of 15 larvae per vial. These vials were subsequently monitored for pupation and eclosion, and the pre-adult survivorship after feeding for different periods of time noted. Using information from this assay as a rough guide, a second assay was carried out after 68 generations of ACU selection to measure the dry weight at eclosion of ACU and AB flies that had fed as larvae for different durations of time (feeding for 54, 56, 59 and 62 h for AB, and 50, 55, 58 and 60 h for ACU populations, respectively). These feeding durations were observed to roughly (±4–5%) correspond to pre-adult survivorship of 13, 25, 50 and 60%, respectively, in both sets of populations. Freshly hatched larvae were collected, shifted to yeast and then removed and placed into agar vials after feeding for these different durations, exactly as described above. Once eclosions began in the agar vials, flies were collected every 4 h and frozen for subsequent weighing. Frozen flies were sorted in batches of five males or five females each and dried at 70°C for 36 h before weighing in batches.

Statistical analyses

Since assays on ACU/AB and NCU/NB populations were conducted at different times, data from the two species were analysed separately. All traits were subjected to completely randomized block analysis of variance (ANOVA). All ANOVAs treated replicate population 1..4 (representing ancestry) as random blocks crossed with the fixed factor selection regime. Additional fixed factors crossed with both selection regime and block, were included when relevant. These factors were larval density and type of culture (single- or two-species) for pre-adult survivorship, pre-adult life stage for life stage duration, urea or ammonia concentration in the food for urea and ammonia tolerance, and larval feeding duration or survivorship for the assays on minimum critical feeding time and of dry weight at eclosion after feeding for different time durations corresponding to four different pre-adult survivorship levels. Development time data from low and high density were analysed separately, rather than incorporating larval density as a factor, because the low and high density assays were conducted at different times for each species. Data on pre-adult survivorship were arcsine squareroot transformed before ANOVA. For all traits, ANOVAs were performed on replicate population mean values and, therefore, only fixed factor effects and interactions could be tested for significance. All analyses were implemented using Statistica for Windows rel.5.0 B, (Stat Soft 1995). Multiple comparisons were done using Tukey's HSD test.

Results

Pre-adult survivorship

Pre-adult survivorship at high larval density is the primary trait expected to be under direct selection in populations exposed to high larval crowding each generation. With regard to survivorship at low versus high larval density, the broad pattern of results was very similar in the two species (figure 1). In both species, pre-adult survivorship was, on an average, significantly higher at low rather than at high larval density, and in selected compared to control populations (figure 1; table 1). The trend was for survivorship to be

Figure 1. Mean pre-adult survivorship at low and high larval densities in the selected and control populations of the two species when cultured alone or in the presence of equal numbers of eggs of white-eyed *D. melanogaster* competitors. Error bars are standard errors around the mean of the four replicate population mean values. Significant differences between pairs of means are indicated by labelling them with different letters. For both species, as the three-way interaction between type of culture, selection regime and larval density was not significant, only the difference between the mean pre-adult survivorships of selected and control populations at high and low larval densities, averaged over type of culture (single- or two species), is highlighted.

Table 1. Summary of results of four-way ANOVA on mean arcsin squareroot transformed pre-adult survivorship at low and high density in the two sets of selected populations and controls in single-species cultures and in two-species competitive cultures with equal numbers of white-eye *D. melanogaster* eggs. Since the analysis was done on population means, block and interactions involving block were not tested for significance.

Culture type × density	10.03	0.05	17.46	0.03
Selection × density	525.03	<0.01	60.88	<0.01
Culture type × selection × density	2.94	0.19	2.12	0.24

higher, on average, in single-species cultures than in two-species cultures, but the difference was significant only in the case of *D. ananassae* (table 1). Both species showed a significant selection regime × larval density interaction (table 1), with the survivorship of selected and control populations not differing significantly at low density, and with selected populations showing significantly higher survivorship than controls at high density (figure 1). Both species showed a significant culture type × larval density interaction (table 1). In *D. ananassae*, averaged over selection regimes, survivorship at low density in both types of cultures (single- or two-species) was similar, whereas survivorship at high density was significantly greater in single-species than two-species cultures (figure 1). In *D. n. nasuta*, an opposite pattern was seen. Averaged over selection regime, survivorship at low density in single-species cultures was higher than in two-species cultures (figure 1), but not significantly so. However, at high density, survivorship in two-species cultures was higher than in single-species cultures, but, again, not significantly so. In fact, the only clear significant difference in the multiple comparisons was that between single-species cultures at low and high densities (figure 1). In the case of *D. ananassae*, there was also a significant culture type × selection regime interaction (table 1), but the only clear significant differences in multiple comparisons were between survivorship in two-species cultures at high density on one hand and in the other three culture type × selection regime combinations on the other (figure 1).

Pre-adult development time

In general, pre-adult development time in *D. n. nasuta* was higher than that in *D. ananassae*, as also noted earlier (Sharmila Bharathi *et al.* 2004). Pre-adult development time was, in general, greater in males than in females and greater at high rather than low larval density, as is usually the case in *Drosophila* (figures 2 and 3; table 2).

Interestingly, in both species at both larval densities, there was a significant main effect of selection regime,

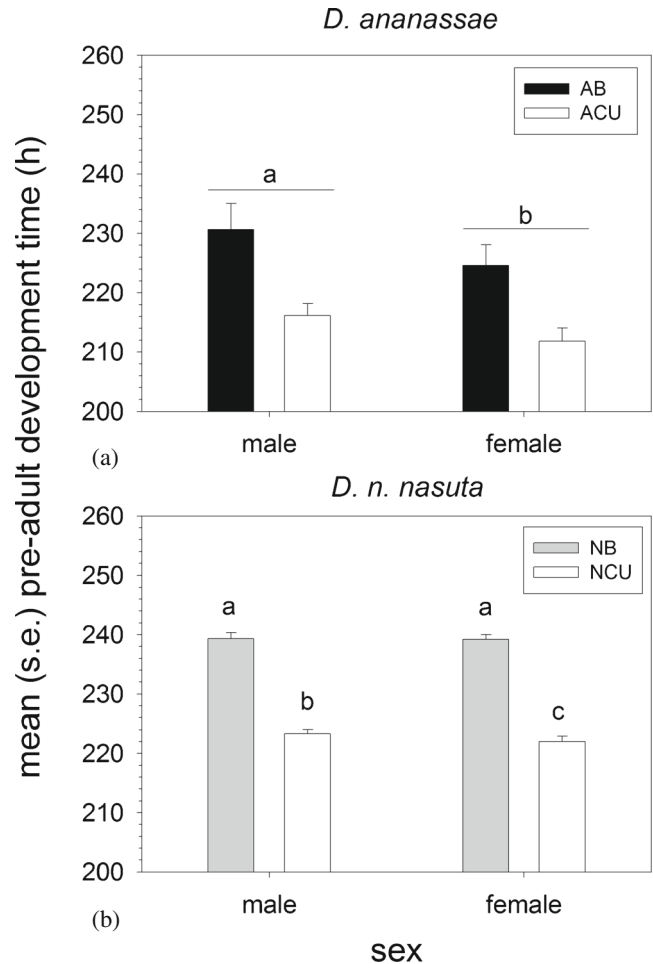

Figure 2. Mean male and female pre-adult development time at low larval density in the selected and control populations of the two species. Error bars are standard errors around the mean of the four replicate population mean values. For both species, significant differences between pairs of means are indicated by labelling them with different letters. For *D. ananassae*, as the interaction between sex and selection regime was not significant, only the difference between the mean pre-adult development time of males and females averaged over selection regimes is highlighted.

with selected populations consistently showing substantially lower development time than control populations at both densities (figures 2 and 3; table 2). On an average, AB development time was higher than that of ACU populations by about 14 and 29 h at low and high larval density, respectively (figures 2a and 3a), whereas that of NB populations was greater than that of NCU populations by about 17 and 29 h at low and high larval density, respectively (figures 2b and 3b). In three of the four assays, there was no significant selection regime × sex interaction (table 2). In *D. n. nasuta* at high larval density, control males and females had similar development times whereas NCU males had significantly higher development time than NCU females, albeit by just about 1 h (figure 3b).

**(a)** *D. ananassae*

(b) *D. n. nasuta*

Figure 4. Mean duration in hours of different pre-adult life-stages at low larval density in the selected and control populations of the two species. Error bars are standard errors around the mean of the four replicate population mean values. For each species, significant differences between pairs of means are indicated by labelling them with different letters. For *D. ananassae*, the interaction between selection regime and life-stage was not significant. Consequently, only the differences in mean duration between life-stages, averaged over block and selection regime have been highlighted.

in general. Consistent with the pre-adult development time results, both species showed a main effect of selection regime (table 3), with life-stage durations being greater in control rather than selected populations, on an average (figure 4). In *D. ananassae*, a 20 h egg stage was followed by two larval instars of about 24 h each, a third larval instar of about 46 h and a pupal stage lasting about 87 h (figure 4a); there was no significant selection regime × life-stage duration interaction. In *D. n. nasuta*, all pre-adult life stages differed significantly from one another in duration with a 23 h egg stage followed by two larval instars of about 27 and 29 h, respectively, a longer third larval instar of about 63 h and a pupal stage lasting about 87 h (figure 4b). The longer larval instar durations in *D. n. nasuta* are consistent with their larger adult size compared to *D. ananassae* (Sharmila Bharathi *et al.* 2004). *D. n. nasuta* also showed a significant selection regime × life-stage duration interaction (table 3), with a large (∼12 h) reduction in third instar duration in the NCU populations (figure 4b). We note that, given the time interval between subsequent observations (1 h for egg-hatch; 2 h for larval instars), our screening might be too coarse to pick up small but consistent differences on the order of 30 min–1 h. However, the differences between selected and control populations in the durations of different pre-adult life-stages, though often not significant, did add up roughly to the overall difference seen in pre-adult development time between selected and control populations in both species.

Larval traits

Surprisingly, larval feeding rate did not differ significantly between selected and control populations in either species (table 4). Mean (±s.e.) larval feeding rates in sclerite retractions per minute were in fact extremely similar between selected and control populations of both species (AB, 128.33 ± 3.13; ACU, 131.55 ± 3.05; NB, 112.76 ± 5.29; NCU, 113.03 ± 4.34). In both species, selected populations showed significantly greater mean (± s.e.) pupation height in centimetre than control populations (AB, 1.02 ± 0.28; ACU, 1.60 ± 0.20; NB, 0.44 ± 0.12; NCU, 1.54 ± 0.11) (table 4). In case of larval foraging path length, the results varied between species, with *D. ananassae* showing a significant

main effect of selection regime while *D. n. nasuta* did not (table 4). AB populations had mean (± s.e.) foraging path length in centimetre of 5.52 ± 0.61 compared to 7.38 ± 0.60 in the ACU populations. NB and NCU populations had mean (± s.e.) foraging path length in centimetre of 4.24 ± 0.53 and 4.08 ± 0.43, respectively.

Larval urea and ammonia tolerance

There was no clear pattern to the results of assays on pre-adult survivorship in the presence of metabolic wastes like urea (figure 5) and ammonia (figure 6) in the food medium, except for strong evidence for the toxic effects of these compounds, reflected in significant main effects of concentration in all four ANOVAs (table 5).

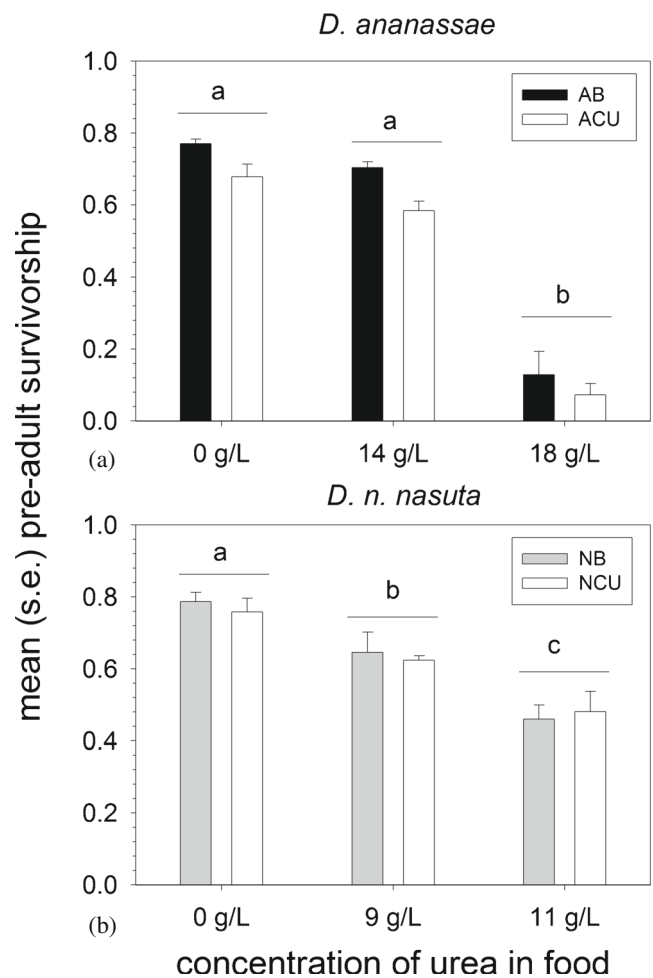

Figure 5. Mean pre-adult survivorship at low density with three different levels of urea in the food medium in the selected and control populations of the two species. Error bars are standard errors around the mean of the four replicate population mean values. For each species, significant differences between pairs of means are indicated by labelling them with different letters. For both species, the interaction between selection regime and urea level was not significant. Consequently, only the differences between mean survivorship at different urea levels averaged over block and selection regime have been highlighted.

Table 4. Summary of the results of two way ANOVA on mean larval feeding rate, foraging path length and pupation height in the two sets of selected populations and controls. Since the analysis was done on population means, block and interactions involving block were not tested for significance; only the F and P values for the main effect of selection regime are shown.

Trait	ACU/AB		NCU/NB	
	$F_{1,3}$	P	$F_{1,3}$	P
Feeding rate	0.54	0.52	0.06	0.82
Foraging path length	94.51	<0.01	0.48	0.54
Pupation height	18.12	0.02	51.62	<0.01

ACU populations had lower survivorship than AB controls across all levels of urea including 0 g/L, and thus showed no evidence of greater or lesser urea tolerance than the AB controls (figure 5a), with a significant main effect of selection regime but no significant selection regime × concentration interaction (table 5). There was suggestive evidence for greater ammonia tolerance in the ACU compared to the AB populations (figure 6a). At 0 g/L of ammonia in the food, ACU populations had significantly lower survivorship than AB controls, whereas at 30 g/L, the ACU survivorship was higher, though not significantly so, than the AB survivorship (figure 6a). The selection regime × concentration interaction was also significant for this assay (table 5).

Table 5. Summary of the results of three way ANOVA on mean arcsin squareroot transformed pre-adult survivorship at three different concentrations of urea or ammonia in the food medium in the two sets of selected populations and controls. Since the analysis was done on population means, block and interactions involving block were not tested for significance.

	ACU/AB		NCU/NB	
Effect	$F_{1,3 \text{ sel}/2,6 \text{ else}}$	P	$F_{1,3 \text{ sel}/2,6 \text{ else}}$	P
Urea tolerance				
Selection	20.39	0.02	0.14	0.73
Concentration	54.77	<0.01	24.88	<0.01
Selection × concentration	0.51	0.62	0.32	0.74
Ammonia tolerance				
Selection	0.14	0.73	45.29	0.73
Concentration	199.34	<0.01	417.76	<0.01
Selection × concentration	14.97	0.02	0.88	0.46

In the case of *D. n. nasuta*, there was no significant effect of selection regime or of the selection regime × concentration interaction in the urea tolerance assay (table 5). However, there was a nonsignificant trend of NCU survivorship being lower than NB at 0 g/L and higher than NB at 11 g/L (figure 5b). In case of ammonia, NCU populations had consistently lower survivorship than NB controls at all concentrations (figure 6b) and there was no significant effect of selection regime or of the selection regime × concentration interaction, yielding no suggestion of increased ammonia tolerance in the NCU populations.

Minimum critical feeding time

In the minimum critical feeding time assay, only significant main effects of selection regime and feeding duration were seen (table 6) with pre-adult survivorship increasing with feeding durations from 46–55 h, and with ACU survivorship being higher than that of the AB populations at every feeding duration (figure 7a). At 55 h of feeding as larvae, ACU survivorship was over 50% while that of the AB populations was less than 30% (figure 7a). Overall, ACU populations seemed to attain similar levels of survivorship ∼6 h before the AB controls (figure 7a), which is commensurate with the 5.48 h difference between their first and second instar durations combined. These results suggest that larvae in the ACU populations attain their minimum critical size for pupation ∼5–6 h before their AB controls.

In the ANOVA on data from the assay of dry weight at eclosion of individuals that had fed for different durations of time as larvae, corresponding to four different levels of pre-adult survivorship, only the main effects of sex and survivorship were significant (table 6). On an average, females were significantly heavier than males, and dry weight at eclosion tend to increase with survivorship (figure 7b). At no survivorship level was there a significant difference between the dry weights of AB and ACU flies (figure 7b), suggesting that the

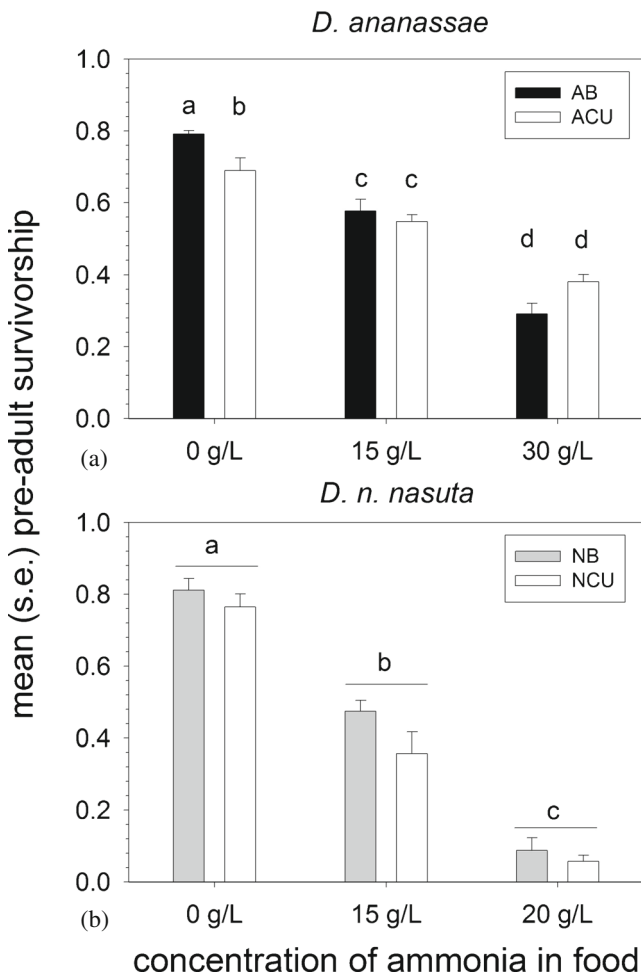

Figure 6. Mean pre-adult survivorship at low density with three different levels of ammonia in the food medium in the selected and control populations of the two species. Error bars are standard errors around the mean of the four replicate population mean values. For each species, significant differences between pairs of means are indicated by labelling them with different letters. For *D. n. nasuta* the interaction between selection regime and ammonia level was not significant. Consequently, only the differences between mean survivorship at different ammonia levels averaged over block and selection regime have been highlighted.

Minimum critical feeding time

(a)

Dry weight at different survivorship levels corresponding to different feeding durations

(b)

Figure 7. (a) Mean pre-adult survivorship after larval feeding for different amounts of time, and (b) mean dry weight (in 10^{-3}g) at eclosion after larval feeding for different amounts of time corresponding to four different mean pre-adult survivorship levels in the *D. ananassae* selected and control populations. Error bars are standard errors around the mean of the four replicate population mean values. For both traits, significant differences between pairs of means are indicated by labelling them with different letters. For both traits, the interaction between selection regime and feeding duration/survivorship was not significant. Consequently, only the differences in mean survivorship between the different levels of feeding duration and differences in mean dry weight at eclosion at different levels of survivorship averaged over block selection regime and sex have been highlighted.

minimum critical size for pupation in the selected and control populations is probably not different, even though the ACU populations attain it faster than the AB controls.

Discussion

It is clear that both ACU and NCU populations did evolve adaptations to larval crowding over the course of selection: in both species, pre-adult survivorship at high density and

competitive ability was greater in selected than in control populations (figure 1; table 1). The overall pattern of correlated responses to selection in the two species was also similar, and, more importantly, different from that reported earlier in case of *D. melanogaster* in that it did not involve the evolution of higher feeding rates (table 4).

In clear contrast to what was seen earlier in *D. melanoagster*, both ACU and NCU populations evolved faster pre-adult development time than their controls (table 2), with the difference being apparent at both low (figure 2) and high (figure 3) assay density. The pre-adult development time difference between selected and control populations is entirely due to reduction in the duration of larval instars (figure 4). In absolute terms, the reductions in pre-adult development time in the selected populations (∼14 h in ACU, ∼17 h in NCU) are quite large. For comparison, populations of *D. melanogaster* subjected to strong directional selection for reduced pre-adult development time showed a reduction of ∼16 h in the larval duration, and ∼10 h in pupal duration, after 50 generations of selection (Prasad *et al.* 2001). In the earlier studies on *D. melanogaster*, CU populations showed no difference from controls in development time at low density, whereas they developed faster than controls when assayed at high density (Borash and Ho 2001). While the *K*-populations did show faster development than *r*-populations when assayed at low density (Bierbaum *et al.* 1989), this cannot be unequivocally ascribed to density-dependent selection. The *K*-populations were on an overlapping generation maintenance regime and, relative to a discrete generation regime like that of the *r*-populations, this itself would impose direct selection for faster development. If we put the results on life-stage duration (figure 4) and development time (figures 2 and 3) together with those from the minimum feeding time assay (figure 7), the ACU and NCU populations have evolved faster development, especially in the first two larval instars, enabling them to reach the critical minimum size for pupation about 6 h earlier than controls. This is particularly impressive considering that *D. melanogaster* populations selected directly for rapid development reached the critical size only about 2 h before controls after 50 generations of selection (Prasad *et al.* 2001). At the same time, the weights of ACU and NCU flies were not different from controls after feeding for different durations close to the minimum feeding time (figure 7; table 6). Thus, in terms of time, ACU and NCU larvae are clearly more efficient at converting food to biomass than controls during the first two (and an early part of the third) larval instars, becoming equally heavy as control larvae after feeding for about 6 h less. Of course, whether they are also more efficient in terms of food consumed cannot be determined from these experiments. However, these results do suggest that, unlike the *K*- and CU populations (Mueller 1990; Joshi and Mueller 1996), the ACU and NCU populations have evolved to become more efficient rather than less efficient than controls. The faster development of the ACU and NCU populations relative to controls is also interesting in the context

Table 6. Summary of the results of three way ANOVA on mean arcisn squareroot transformed pre-adult survivorship (factors: block, selection regime and larval feeding duration) and mean dry weight (factors: block, selection regime, sex and pre-adult survivorship) of eclosing flies after larvae were allowed to feed for different time periods in the AB and ACU populations. Since the analysis was done on population means, block and interactions involving block were not tested for significance.

Effect	Survivorship		Dry weight	
	$F_{1,3 \text{ sel}/3,9 \text{ else}}$	P	$F_{1,3 \text{ sel}/3,9 \text{ else}}$	P
Selection	174.79	<0.01	0.01	0.94
feeding duration (for survivorship)	37.07	<0.01		
Survivorship (for dry weight)			16.39	<0.01
Sex (for dry weight)			223.27	<0.01
Selection × feeding duration (for survivorship)	0.35	0.78		
Selection × survivorship (for dry weight)			2.76	0.10
Selection × sex (for dry weight)			3.25	0.17
Survivorship × sex (for dry weight)			1.40	0.30
Selection × survivorship × sex (for dry weight)			0.48	0.71

of observations that faster development correlates with greater competitive ability across species of *Drosophila* (Krijger *et al.* 2001), even though direct selection for rapid development leads to the evolution of reduced competitive ability (Shakarad *et al.* 2005) through reduced larval feeding rate, foraging path length and pupation height (Prasad *et al.* 2001), as well as reduced larval urea tolerance (Joshi *et al.* 2001).

Unlike in *D. melanogaster*, larval feeding rates did not evolve to become greater in ACU and NCU populations (table 4), although these populations clearly evolved greater competitive ability than controls (figure 1). In fact, we measured feeding rates at various points during ACU and NCU selection, and also at various larval stages, and there was never any difference between selected and control populations in either species (data not shown). Interestingly, larval foraging path length was greater in ACU populations than in AB populations, whereas NCU and NB populations had very similar foraging path lengths (table 4). Thus, at least in *D. ananassae*, the consistent positive relationship between larval feeding rate and foraging path length seen in *D. melanogaster* (Joshi and Mueller 1988, 1996; Sokolowski *et al.* 1997; Borash *et al.* 2000; Prasad *et al.* 2001; Mueller *et al.* 2005) seems to be uncoupled. Pupation height evolved to become greater in both ACU and NCU populations, relative to controls, mirroring results from the *K*-populations (Mueller and Sweet 1986), but not the CU populations (Joshi and Mueller 1996; but see also Mueller *et al.* 1993 and Joshi *et al.* 2003). One possible reason for the evolution of increased pupation height in the *K*-populations but not the CU populations has been speculated to be the greater hardness and dryness of the cornmeal-based food (*r*- and *K*-populations) compared to banana based food (UU and CU populations). It was suggested that banana food being much softer and more fluid compared to cornmeal food, perhaps, the UU populations were also under selection for increased pupation

height due to greater risk of pupal drowning on the food surface even at their relatively low rearing density (Joshi *et al.* 2003). In this context, we note that our ACU/AB and NCU/NB populations are maintained on a relatively hard and dry cornmeal food and this might be the reason for the evolution of greater pupation height in selected populations, relative to controls.

Compared to other traits, the results on urea and ammonia tolerance in the selected and control populations were not very clear. While pre-adult survivorship clearly decreased with increasing amounts of urea or ammonia in the food (figures 5 and 6; table 5), there was no clear evidence for greater urea or ammonia tolerance in the selected populations, except for greater ammonia tolerance in the ACU populations, relative to the AB controls (figure 6a). There was a slight suggestion of a trend towards increased urea tolerance in the NCU populations, relative to NB controls in that NCU survivorship at 0 g/L was below that of NB populations and became slightly higher than NB populations at 11 g/L (figure 5b). However, there was no significant selection regime × urea concentration interaction (table 5), indicating that this is at best a suggestive result. It might be that crowded *D. ananassae* and *D. n. nasuta* cultures have experienced differential levels of urea versus ammonia buildup to which they have adapted. Moreover, we have seen, in other studies with *D. melanogaster*, that the detection of between population differences in urea/ammonia tolerance is often affected by an interaction between the specific concentrations used and the larval density (Avani Mital, Gitanjali P. Vaidya and Amitabh Joshi, unpublished data). It is, therefore, possible that we were unable to detect significant differences between selected and control populations due to the specific concentrations and larval densities used in our assays of urea and ammonia tolerance. It is also known that larval exposure to urea markedly reduces subsequent fecundity in

D. melanogaster, and that populations selected for increased larval urea tolerance undergo smaller fecundity declines than controls when reared as larvae on food with urea (Shiotsugu *et al.* 1997). Thus, it is also possible that the ACU and NCU populations might have evolved greater tolerance to the detrimental effects of urea on fecundity; our experiments did not explore this possibility.

Overall, the crowded *D. ananassae* and *D. n. nasuta* populations seem to have evolved greater competitive ability and pre-adult survivorship at high density primarily through a combination of reduced duration of the larval stage, faster attainment of minimum critical size for pupation, greater efficiency of food conversion to biomass, increased pupation height and, perhaps, slightly greater urea/ammonia tolerance. This is in contrast to *D. melanogaster*, in which crowding adapted populations evolve greater competitive ability and pre-adult survivorship at high density primarily through a combination of increased larval feeding rate and foraging path length, at the cost of reduced efficiency of food conversion to biomass, and greater urea/ammonia tolerance (Mueller 1997; Prasad and Joshi 2003; Mueller 2009). Thus, the ACU and NCU populations appear to have responded to crowding in a manner closer to the canonical notion of *K*-selection, in contrast to the primarily *α*-selection responses shown by the *K*- and CU populations of *D. melanogaster* (see also Dey *et al.* 2012). Thus, the results underscore the fact that there are, in principle, multiple routes to the evolution of greater competitive ability (Joshi *et al.* 2001; Dey *et al.* 2012), something that has also been experimentally demonstrated in the context of interspecific competition in *Drosophila* (Joshi and Thompson 1995).

At this point, we can only speculate about the reason(s) for why the evolution of increased competitive ability in ACU and NCU populations occurred in a manner so different from that seen earlier in *D. melanogaster*. We believe that there are three possible reasons for the observed discrepancy in correlated responses to selection for adaptation to larval crowding across the three species, and the three proposed explanations are not mutually exclusive. First, it is possible that the pattern of genetic variances and covariances among traits relevant to survival in a crowded culture is different from that of *D. melanogaster* in the two species studied here (*D. ananassae* and *D. n. nasuta*). For example, maybe the AB and NB populations do not harbour additive genetic variance for larval feeding rate. Such differences of genetic architecture could simply reflect between-species differences, being the result of historical selection pressures and contingencies. However, if that were the case, we would have expected the results from *D. ananassae* to be closer to *D. melanogaster*, as compared to *D. n. nasuta*, given the phylogenetic and ecological relationships of these species (see Introduction, last paragraph). A second, more likely, possibility is that these differences of genetic architecture between *D. ananassae* and *D. n. nasuta* on the one hand, and *D. melanogaster* on the other, are because the ACU and NCU populations represent selection on relatively recently wild-caught populations

(see Materials and methods), whereas the *K*- and CU populations involved selection on populations that had already been in the laboratory for a large number of generations (Mueller and Ayala 1981; Joshi and Mueller 1996). There might be significant differences in the genetic architecture of traits related to fitness under larval crowding between wild and laboratory populations. Finally, it is possible that the discrepancies between the results of this study and those from earlier work on *D. melanogaster* are due to differences in the specific details of the respective maintenance regimes of selected populations in the various studies. Such small differences in selection regimes have been implicated in the different trajectories of pupation height in the *K*- versus CU populations (Joshi *et al.* 2003). The *K*-populations were maintained on a serial transfer system in half-pint milk bottles with about 350 mL food per bottle (Mueller and Ayala 1981), while the CU populations were maintained in 6 dram vials (2.2 cm diameter) at a density of about 1000–1500 eggs per vial in about 5 mL of food. Unlike in our ACU and NCU populations, neither food amount nor number of eggs per vial was exactly controlled in CU maintenance. In the CU populations, eggs were laid by adult females onto thin films of food on four watch glasses per cage. These film of food with eggs on them were then sliced up and divided roughly equally among 40 vials that each contained about 3 mL of food (A. Joshi, personal observation). Thus, our ACU and NCU populations had a smaller absolute amount of food per rearing container (bottle/vial) than the *K*- and CU populations, and also differed from the latter in specific densities of eggs per mL of food. It is, therefore, possible that the time course of food depletion and nitrogenous waste build-up in the ACU and NCU cultures is somewhat different from that of *K*- and CU populations. It has been shown theoretically that optimal feeding rates are likely to decline as the concentration of nitrogenous waste in the food increases (Mueller *et al.* 2005). Thus, at least, in principle, it is possible that the optimal feeding rates in the ACU and NCU populations are actually less than they were for *K*- and CU populations, and that is why increased feeding rates did not evolve in our experiments. Subsequent studies will attempt to discriminate between these various explanations. However, for the time being, we believe that these results underscore the need for a more nuanced understanding of adaptations to larval crowding in *Drosophila* with a greater appreciation for the fact that increased competitive ability can be attained through the evolution of fairly different suites of traits. We also need to be cognizant of the fact that seemingly small differences of maintenance in otherwise similar selection regimes might mediate the evolution of very different trajectories in phenotypic space.
