PROSPECTIVE CAUSAL GENES FOR GENETIC GENERALIZED EPILEPSY

A thesis submitted for the degree of

Doctor of Philosophy

By

MANPREET KAUR

Molecular Biology and Genetics Unit
Jawaharlal Nehru Centre for Advanced Scientific Research
(A Deemed University)
Bangalore 560 064, India

December 2014

Dedicated to…

Patients and their families

and

my parents

Declaration

I hereby declare that this thesis, entitled ***"Prospective causal genes for genetic generalized epilepsy",*** *is an authentic record of research work carried out by me under the guidance of Prof. Anuranjan Anand in the Molecular Biology and Genetics Unit, Jawaharlal Nehru Centre for Advanced Scientific Research, Bangalore, India and that this work has not been submitted elsewhere for the award of any other degree.*

In keeping the norm of reporting scientific observations, due acknowledgements has been made wherever the work described here has been based on the findings of other investigators. Any omission, which might have occurred by oversight or misjudgment, is regretted.

Manpreet Kaur

Place: Bangalore
Date:

Certificate

This is to certify that the work described in this thesis entitled ***"Prospective causal genes for genetic generalized epilepsy"*** *is the result of the investigations carried out by Ms. Manpreet Kaur in the Molecular Biology and Genetics Unit, Jawaharlal Nehru Centre for Advanced Scientific Research, Bangalore, India, under my guidance, and that the results presented in this thesis have not previously formed the basis for the award of any other diploma, degree or fellowship.*

Prof. Anuranjan Anand

Acknowledgements

One of the joys of completion is to look over and thank all the people who have helped and supported me along this long but fulfilling journey.

First and foremost I express my gratitude to my advisor and mentor, Prof. Anuranjan Anand. His guidance and support provided throughout the duration of my PhD has been a constant source of inspiration. I thank him for giving me an opportunity to work on exciting projects and exceptional freedom to plan and shape the work. He has immensely helped me improve my presentation and scientific writing skills. It is his patience and support that helped me academically and emotionally throughout the road to finish this thesis.

I would like to thank Prof. MRS Rao, former chairman of Molecular Biology and Genetics Unit (MBGU), JNCASR, for his valuable suggestions during the work presentations in the department. Thanks to the faculty members of MBGU, Prof. Ranga Uday Kumar, Prof. Hemalatha Balaram, Prof. Namita Surolia, Prof. Tapas K. Kundu, Prof. Maneesha Inamdar, Prof. Kaustuv Sanyal, Dr. Ravi Manjithaya and Dr. James P. Clement Chelliah, for their encouragement and suggestions during the work presentations and also for the useful interactions, I had with them.

I would take this opportunity to thank all our clinical collaborators from NIMHANS, SCTIMST and other epilepsy specialty clinics- Drs. KS Mani, P Satishchandra, S K Shankar, K Radhakrishnan, G Kuruttukulam, Girish Gadre and Dilip KS- for their hard work in collecting the samples used in this study.

I acknowledge Dr. M C Raja, Dr. Vidya, S Selvanayagam and M Ashick of Genotypic Technology, Bangalore for conducting the next-generation sequencing of four samples and the preliminary data analysis.

I thank all my past and present labmates: Ashish, Ram, Aparna, Rinki, Nishtha, Chandra, Meenakshi, Rammurthy, Mohan, Arunima, Rekha, Ramesh, Rahul, Praveen, Kalpita, Shalini, Shveta, Sourav, Pooja and Shrilaxmi. I thank them for creating an intellectually stimulating and pleasant work environment in the laboratory. For my friend, Nishtha, I fall short of words to thank her for the

emotional support she has given me during the rough times in this journey. Additionally, I acknowledge the summer/short-term trainees, Shweta, Rajshree, Goirik, Pooja and Ankita, whom I had the opportunity to mentor, for their contribution in the work.

My stay at JNC, far away from my home, has been an enjoyable and enriching experience with various academic and cultural activities taking place and around diverse people from different parts of the country. I thank my friends, Swaroopa, Nikhil, Shreoshi, Nisha and Pooja, who have helped and supported me time and again, and made this stay a memorable one. I thank a few of the JNCites I shared some interesting times with: Gayatri, Ronak, Laxmi Shanker, Gautam, Abhishek, Rahul Modak, Anand, Selvi, Bharath, Mangai, Vijay J, Amrutha, Gopal, Arpit, Sanjeev, Sourav, Lakshmeesha, Rohan, Anjali, Neha, Piyush, Vijay V, Vini, Priyanka, Meha.

I acknowledge support from the confocal and sequencing facility at MBGU, computer lab, library, academic section, administration section, health and hostel facility of JNCASR. Thanks to Ms. Anitha, Ms. Suma, Dr. Archana, Dr. Subba Rao, Dr. Princy, Ms. Sukanya and Mr. Gururaj, for their help throughout my stay here. I acknowledge financial assistance provided by CSIR and JNCASR. Travel grant supports from DBT for ASHG 2013 and Nanion Technologies for Port-a-patch training is gratefully acknowledged.

No words can describe my gratitude to my parents and family for their constant love, encouragement, support and trust. I thank them for being with me through all phases of my life and without their support; I most certainly would not have reached here. In particular, I thank my husband, Tarvinder for his unconditional love and support.

Finally, I would like to thank all the patients and their family members, to whom I dedicate this thesis, for their participation, which made this work possible.

Above all, I thank the almighty God and my Guru Ji for everything.

Chapter 1

Introduction

Epilepsy is a group of neurological disorders defined by recurrent and unprovoked epileptic seizures. According to the most recent clinical definition of epilepsy by International League Against Epilepsy (ILAE), an individual may be considered epileptic when any of the following criteria are met: (i) at least two unprovoked or reflex seizures occurring >24 h apart; (ii) one unprovoked or reflex seizure and a probability of further seizures similar to the general recurrence risk (at least 60%) after two unprovoked seizures, occurring over the next 10 years; (iii) diagnosis of an epilepsy syndrome (Fisher et al 2014). An epileptic seizure, in turn, is a transient occurrence of symptoms due to abnormal excessive or synchronous neuronal activity in brain, which is usually intermittent, self-limiting and occur with or without loss of consciousness. Unprovoked epileptic seizures may occur unpredictably and are not caused due to factors such as head trauma, stroke, intracranial infections, acute metabolic abnormalities and drug or toxin poisoning.

Present day understanding and concepts of epilepsy and seizure originated from the contributions of Robert Bentley Todd and John Hughlings Jackson in 1850s (York and Steinberg 2011). The work and clinical observations of Hughlings Jackson, a physician, advocated for the understanding of different seizure types and laid the foundation for a scientific approach to the study of epilepsies. The ILAE introduced the classification and terminology for different types of epilepsies and seizures and published it in 1960. These were updated in the classifications of epileptic seizures in 1981 (Commission on Classification and Terminology of the International League Against Epilepsy 1981) and in 1989 (Commission on Classification and Terminology of the International League Against Epilepsy 1989). The most recent revision of terminology and classification of seizure types

and different forms of epilepsies were reported in 2010 (Report of the ILAE Commission on Classification and Terminology 2005–2009, Berg et al 2010).

The widely accepted terminology of epileptic seizures in both basic and clinical research is of two types: focal or partial epilepsy and generalized epilepsy. Focal seizures originate primarily in one hemisphere of the brain, which may be localized to a region or widely distributed. These are further subdivided, according to impairment of consciousness during the seizure episode into simple partial seizures, complex partial seizures and partial seizures evolving to generalized seizures. However, the revised seizure classification suggests description of focal seizures according to specific manifestations such as subjective (auras), motor, autonomic, and dyscognitive features (Berg et al 2010). Generalized epileptic seizures originate from bilateral networks involving both the brain hemispheres and include absences, myoclonus, tonic, atonic, clonic and primary generalized tonic clonic seizures.

The concept of epilepsy syndrome was given in 1989 and is defined as a "cluster of signs and symptoms customarily occurring together; including factors such as type of seizure, etiology, anatomy, precipitating factors, age of onset, severity, chronicity, diurnal and circadian cycling, and sometimes prognosis". The 1989 classification organizes forms of epilepsy syndromes in three classes: idiopathic, symptomatic and cryptogenic depending on their characteristics and the cause of manifestation. Whereas, the revised classifications incorporate additional criteria to categorize epilepsies on the basis of etiology into "genetic" (with presumed underlying genetic defect), "structural/metabolic" (associated with distinct structural or metabolic disease) and "unknown" (underlying cause is not yet known) (Berg et al 2010). Each class can further be organized on the basis of age of onset, specific underlying cause etc.

1.1 Genetic Generalized Epilepsies (GGE)

Genetic generalized epilepsies (GGE) constitute a heterogeneous group of epilepsies with generalized seizures, and are associated with bilaterally

synchronous and symmetrical EEG discharges. GGE syndromes are common and account for 30-40% of all human epilepsies (Sander 1996, Jallon and Latour 2005, Huber et al 2009). They are usually not associated with any brain lesions, mental impairment or neurological abnormalities other than seizures. This group of epilepsies was formerly called "idiopathic epilepsies" and is now often termed as "genetic epilepsies" (Berg and Scheffer 2011) due to absence of any apparent etiology other than a strong possibility of genetic predisposition. GGE represent electro-clinical syndromes, in which a combination of clinical features such as seizure types, age of onset and electroencephalogram (EEG) features (generalized spike wave discharges) are required for diagnosis.

The classical GGEs are divided based on the age of onset and the type of seizure, into four common sub-syndromes: childhood absence epilepsy (CAE), juvenile absence epilepsy (JAE), juvenile myoclonic epilepsy (JME) and epilepsy with generalized tonic-clonic seizures (EGTCS). In addition, there are several rare GGE sub-syndromes that include benign myoclonic epilepsy of infancy (BMEI), early onset absence epilepsy, myoclonic astatic epilepsy (MAE), epilepsy with myoclonic absences, eyelid myoclonia with absences and absence status epilepsy (Huber et al 2009). The frequent seizure types associated with GGE are absence seizures, myoclonic seizures and generalized tonic-clonic seizures (Mattson 2003). The EEG trait of generalized spike-waves is the defining factor in the diagnosis of GGE, indicating bilateral synchronous discharges in a normal background.

Genetic determinants are known to play a major role in pathophysiology of GGE. Several twin and family segregation studies have provided evidence for its genetic basis and indicated towards its complex inheritance pattern. Determining the genetic causes of GGE has been challenging due to its complex genetic architecture comprising of multiple genetic factors (polygenic) with or without their interaction with environmental factors. JME is the most common heritable GGE sub-syndrome and has been emphasis of my research interest for this thesis. Therefore, the study presented here focuses largely on this GGE subtype.

1.2 Juvenile Myoclonic Epilepsy (JME)

JME was first 'discovered' in Switzerland and France in the 19th century. The initial cases were reported by Theodore Herpin (Herpin 1867); and Rabot described the characteristics of myoclonic jerks (Rabot 1899). A comprehensive description of JME as a separate clinically defined syndrome was first provided by Janz and Christian, in a report of 47 cases from Germany and the name "impulsive petit mal" was proposed (Janz and Matthes 1955). Subsequently, the term "juvenile myoclonic epilepsy" was coined (Lund 1975) (review by Genton and Gelisse 2013). In 1989, ILAE suggested "juvenile myoclonic epilepsy" and "impulsive petit mal" as equivalent terms to define this clinical entity (ILAE 1989). In the last three decades or so, JME cases have been intensively studied and reported worldwide from different populations (Delgado-Escueta and Bascal 1984, Asconapé and Penry 1984, Murthy et al 1998, Nicoletti et al 1999).

1.2.1 Prevalence and incidence

JME is a relatively common subtype of genetic generalized epilepsy and accounts for 4-11% of all epilepsies (Hauser 1993, Montalenti et al 2001). Based on hospital and clinical records, it has a prevalence of 12%, whereas its population-based prevalence accounts for 3%. The persistent clinical symptoms of JME and its early age-of-onset result in a high prevalence rate in epilepsy speciality clinics than in referral centres. The prevalence rates reported in various studies are 4.3% in Germany (Janz 1969), 2.8% in Brazil (Figueredo et al 1999), 5.5% in Malaysia (Manonmani et al 1999) and 10.7% in Saudi Arabia (Obeid and Panayiotopoulos 1988). In different parts of India, the reported prevalence rates of JME are 9% (Jain et al 2003) in north India, 7.7% (Murthy et al 1998) and 5.9% (Mani and Rangan 1995) in south India. JME apparently has an equal sex distribution but several reports in literature support a slight female preponderance (Janz and Durner 1997, Panagariya et al 2001). A few studies suggest male preponderance as well (Delgado-Escueta 1984, Mehndiratta and Aggarwal 2002, Vijai et al 2003a).

1.2.2 Age of onset

The onset of JME is age-related, generally from age 12 to 18 years, but may vary from 8 years to 26 years. The mean age of seizure onset in patients with JME is 14 ± 2 years, slightly earlier in females than in males (Marini et al 2004) and about 18 years in the affected family members (Cvetkovska et al 2014). In rare cases with the onset occurring outside the range of 8-26 years, diagnosis should be done with caution. In studies from India, the mean age at onset for JME has been reported as 13.4 ± 4.9 years (± SD) (Murthy et al 1998) and 14.1 ± 3.1 years (± SD) (Mehndiratta and Aggarwal 2002). The seizure types for JME comprise myoclonic jerks (MJ), generalized tonic-clonic seizures (GTCS) and absence seizures (Ab). The mean age of onset for absence seizures is 10.5 ± 3.4 years; for myoclonic seizures is 15 ± 3.5 years and for GTCS is 16 ± 3.5 years (Panayiotopoulos et al 1994).

1.2.3 Clinical and neurological characteristics

The characteristic clinical symptom of JME is myoclonic jerks, which are usually accompanied by generalized tonic-clonic and absence seizures. Myoclonic jerks often occur within one hour of awakening and are associated with sleep-awake cycle (Janz and Durner 1997). The seizures can be precipitated by factors such as sleep deprivation, disturbed sleep-awake cycle, fatigue, alcohol intake and photic stimulation (Janz 1985, Pederson and Peterson 1998, Dhanuka et al 2001, da Silva Sousa et al 2005, Welty 2006).

Myoclonic seizures are the leading symptoms of JME and in about 5% of the patients it is the only seizures present (Greenberg et al 1988, Jain et al 1998). The MJ are characterized as short, bilateral mostly symmetric synchronous muscle contractions predominantly involving the extensor muscles of arms and shoulders. A myoclonic jerk is brief and can be single or repetitive, but usually arrhythmic. Consciousness is maintained, but may be impaired during the jerks. Myoclonic jerks generally precede generalized tonic-clonic seizures (GTCS) (clonic-tonic-clonic sequence) in most of the patients, by an average of about two years. GTCS are observed in most (> 90%) of the JME patients (Greenberg et al

1988, Montalenti et al 2001). In studies involving JME patients from India, history of GTCS has been reported in 75.7% (Mehndiratta and Aggarwal 2002) and 92.9% (Vijai et al 2003) of the cases. In a GTCS seizure, whole body is involved and episodes are usually longer and intense. The tonic phase causing stiffening of muscles is followed by clonic phase causing rhythmic and rapid jerks in arms and legs. The tonic-clonic seizure generally lasts 1 to 3 minutes and occurs mainly after awakening, but may also be nocturnal or random. Absence seizures are subtle in revelation and often go unrecognized in JME patients. The absences are clinically represented as transient phases of severe impairment/loss of consciousness reported as flashes of blackouts, momentary lack of concentration or state of non-responsiveness. They may occur several times a day without circadian variation. The frequency and severity of absence seizures is age-dependent, with those of late-onset (>10 years) being less severe. About 10-30% of JME patients manifest absence seizures, beginning at the mean age of 10.5-11.5 years (Janz 1969, Delgado-Escueta 1984, Panayiotopoulos et al 1994). Among studies from India, JME cases reported with absence seizures varied from 8-40% (Jain et al 2003, Murthy et al 1998, Mehndiratta and Aggarwal 2002, Vijai et al 2003a).

General clinical examination of JME patients is usually normal and is not associated with conditions such as head injury, brain tumor, or encephalitis (Janz and Durner 1997). A few structural and functional imaging studies have highlighted the existence of underlying anatomical abnormalities associated with JME (Meencke and Janz 1984, Meencke and Janz 1985). Specialized staining techniques on a few JME patients have revealed grey and white matter abnormalities, collectively known as microdysgenesis (Meencke and Janz 1984, Meencke and Janz 1985). However, pathological significance of these observations remains unknown. At neurotransmission level, impairment in both serotonin (Meschaks et al 2005) and dopamine (Ciumas et al 2008) systems may be involved in its pathophysiology. Advances in the development of highly sensitive neuroimaging techniques and neuroimaging analysis methods have allowed detailed investigation of the underlying structural alterations in brain anatomy of JME patients. Quantitative MRI and molecular imaging studies report

changes in medial prefrontal cortex (Woermann et al 1999, O'Muircheartaigh et al 2011), thalamus (Kim et al 2007, Pulsipher et al 2009), dorsolateral prefrontal cortex (Koepp et al 1997) and increased structural connections between prefrontal cortex and motor cortex (Vollmar et al 2012). These studies suggest alterations and dysfunction in thalamo-frontocortical network as a possible cause of functional impairment in JME (O'Muircheartaigh et al 2012, Wandschneider et al 2012, Koepp et al 2013). Overall, these findings have generated several hypotheses for origin of epileptic discharges such as cortical onset, thalamic onset or corticoreticular onset and indicate that interplay between thalamus and cortex is necessary for generation and maintenance of generalized discharges.

1.2.4 Electroencephalogram (EEG) characteristics

Electroencephalography (EEG) plays an important role in diagnosis and assessment of patients with JME. The EEG pattern for JME shows normal background activity along with typical interictal generalized spike-wave (GSW) and polyspike-wave (PSW) discharges of frequency of 4-6 Hz (Asconape and Penry 1984), with a frontocentral predominance (Rodin et al 1987). The generalized spike-wave discharges (GSWD) may last from less than 3 seconds to more than 30 seconds, and are mostly observed at sleep onset or awakenings. Classical 3 Hz spike-wave complexes or 3 Hz polyspike-wave complexes, characteristic of typical absence seizures, occur in approximately 17% of EEGs. Existence of focal features in generalized discharges is well known and is reported among one-third of GGE/JME patients (Panayiotopoulos et al 1994, Aliberti et al 1994, Usui et al 2005, Jayalakshmi et al 2010, Seneviratne et al 2014). The ictal EEG is characterized by 10- to 16-Hz medium-high amplitude spikes followed by irregular slow waves. The number of spikes ranges from 5 to 20 per episode and correlates with the intensity rather than the duration of each seizure (Janz and Christian 1957). Provocative measures, such as photic stimulation and sleep deprivation, can help elicit the characteristic EEG abnormalities; and conducting the EEG recording during the process of awakening may be necessary for the diagnosis (Janz 1985). Atypical EEG findings in some patients also contribute to the misdiagnosis of JME (Lancman et al 1994, Montalenti et al 2001). The absence of abnormal EEG readings in JME probands is not unusual (Montalenti et al 2001,

Murthy et al 1998, Jain et al 1998). The combination of EEG with functional magnetic resonance imaging (fMRI) and recent advancements in its data analyses offer a high spatial resolution and detailed *in vivo* electrophysiology than routine scalp EEG, giving an insight to redefine pathophysiology of generalized epilepsies (Gotman et al 2006, Gotman 2008, Kay and Szaflarski 2014).

1.2.5 Photoparoxysmal response (PPR)

Photosensitivity or photoparoxysmal response (PPR) is an abnormal electroencephalographic response to intermittent photic stimulation (IPS), indicated as diffuse paroxysmal discharge. It can be described as altered visual contrast gain control or heightened sensitivity to specific wavelengths. Photosensitivity is a frequently observed feature in GGE with a robust association with JME (Kasteleijn-Nolst Trenite 2001, Guerrini and Genton 2004, Seneviratne et al 2012, Koeleman et al 2013). Photosensitivity is reported in 13-18% of idiopathic absence epilepsies and in 30-35% of patients with JME (Wolf and Goosses 1986, Covanis 2005, Kasteleijn-Nolst Trenit 2006). The photic stimulation response can be influenced by several factors such as age, gender, ethnicity, anti-epileptic drug (AED) treatment, genetics, sleep deprivation and the stimulation technique. Moreover, PPR can also be provoked in 90% of patients with JME depending on mode and intensity of IPS (Appleton et al 2000). The prevalence rates of photosensitivity reported in various studies are as follows: 33% in patients from USA (Asconapé and Penry, 1984), 27.3% in patients from Saudi Arabia (Panayiotopoulos et al 1994), 17.5% in patients from Japan (Shiraishi et al 2001) and 54% in 13 families from Macedonia (Cvetkovska et al 2014). The prevalence rates of photosensitivity reported from JME cases in India are 9% (Jain et al 1998) and 11.6% (Mehndiratta and Aggarwal 2002) from north India, 13% (Murthy et al 1998) and 9.9% (Vijai et al 2003a) from south India. PPR is more often seen in the younger age group of patients and in females (Wolf and Goosses 1986, Kasteleijn-Nolst Trenit 1989, Harding and Jeavons 1994). The EEG-fMRI performed during photic stimulation indicates that the photoparoxysmal response in JME patients may be due to pathological network alterations in the striato-thalamocortical system of the brain (Bartolini et al 2014).

1.3 Genetics of juvenile myoclonic epilepsy

Juvenile myoclonic epilepsy is a heritable subtype of genetic generalized epilepsy. Its etiology is primarily genetic in origin and follows both Mendelian and complex modes of inheritance. In JME families, the clinical and EEG traits are largely inherited in an autosomal dominant inheritance pattern. However, the inherited mutant alleles often show incomplete penetrance and lead to phenotypic heterogeneity within families. Several studies indicate complex polygenic genetic architecture of JME suggesting the implicated genes may be modified by additional genes or possibly by environmental factors. To date, a few genes with disease-segregating mutations or susceptibility-conferring alleles have been identified in a rather small number of JME patients, indicating that its genetic determinants are largely undiscovered.

1.3.1 Clinical genetics

A high genetic predisposition associated with genetic generalized epilepsies has been reported by several clinical genetic studies (Janz et al 1989, Vijai et al 2003a, Cvetkovska et al 2014). The clinical genetic data obtained by twin studies and family aggregation studies suggests the genetic contribution of GGE (Helbig et al 2008, Koepp et al 2014). Prevalence of epilepsy in first- and second-degree relatives of the proband and concordance amongst twins indicate a shared genetic factor associated with the disease. The positive family history has been reported in 17-50% of the JME patients with first- or second-degree relatives affected with the same or different subtype of generalized epilepsy (Janz 1985, Mehndiratta and Aggarwal 2002, Vijai et al 2003a, Marini et al 2004). Twin studies compare concordances (presence of disease) in identical (monozygotic) and non-identical (dizygotic) twin pairs. High concordance in monozygotic twins than dizygotic twins has been reported in studies with large number of twin pairs having genetic generalized epilepsy (Berkovic et al 1998, Kjeldsen et al 2003, Vadlamudi et al 2004, Vadlamudi et al 2014), indicative of a strong genetic basis. The studies on multiplex families with several of its members affected with GGE, report heterogeneity in the clinical phenotypes and syndrome subtype as well, possibly due to variable expressivity of the causative mutation (Kapoor et al 2008). So far,

such multi-generational families have been extremely helpful to discover the disease-linked sub-genomic regions and genes in subtypes of generalized epilepsies.

1.3.2 Molecular genetics

Over the past two decades, JME has been a subject of genetic analysis, which has led to identification of several loci and genes (Delgado-Escueta et al 2013, Koepp et al 2014). These studies further support and establish the view of JME as a complex trait which is associated with high genetic and phenotypic heterogeneity. Genetic linkage- and association studies have unravelled genes, loci as well as several susceptibility alleles for JME, reflecting it's monogenic, oligogenic and polygenic genetic architecture.

1.3.2.1 Linkage studies and mutational analysis of candidate genes

JME, a GGE sub-syndrome manifests a complex mode of inheritance and is also inherited in a Mendelian or near-Mendelian manner in multi-generational families. Though, the underlying genetic factor can be a mutation of a large effect responsible for the disease or a rare allele with moderate effect along with modifier alleles resulting in phenotypic and clinical heterogeneity among the affected relatives. So far, linkage studies on such relatively uncommon large multiplex JME families have identified a few loci and genes with disease-segregating mutations in affected family members. However, the mutations in these genes do not account for majority of the JME patients from across different populations. This indicates a complex genetic and polygenic basis of JME, wherein only a small fraction of causative determinants have been deciphered and validated. The family-based linkage studies help by focusing the search to JME-linked specific chromosome loci and filtering the candidate genes to be screened, excluding major part of the exome or genome for involvement in JME.

Screening of candidate genes for mutations is based on a prior hypothesis, and aims at identifying more rare variants in epilepsy patients as compared to control subjects. These genes are normally chosen due to their association with an

epilepsy sub-syndrome or seizure phenotype in either humans or animal models or both (Escayg et al 2000, Arsov et al 2012, Tao et al 2011). So far, both these approaches have led to identification of genetic determinants for JME in a small number of families, and risk alleles remain undefined in about 90% of the patients. Here, I discuss findings regarding a few JME genes where mutations have been discovered in multiplex families using linkage-based studies and mutational analysis of candidate genes. Besides these, findings from a few genome-wide association studies identifying susceptibility loci for GGE/JME are discussed.

1.3.2.1a GABRA1 at EJM5 (5q34)

In a study by Cossette and colleagues, genetic linkage analysis on a French Canadian family with JME mapped the disease-linked region to 5q34 (Cossette et al 2002). A heterozygous mutation leading to Ala322Asp in *GABRA1*, α1 subunit of $GABA_A$ was found in the affected members of the family. $GABA_A$ receptor with the mutant α1 subunit exhibited loss of function phenotype resulting in reduced amplitude of the GABA-evoked currents (Cossette et al 2002) and reduced ligand affinity (Krampfl et al 2005). This was the first report of a gene mutation segregating with JME phenotype in a Mendelian fashion. A cohort of unrelated 35 JME patients from south India showed absence of *GABRA1*, Ala322Asp, suggestive of it being an uncommon cause of JME in south Indian population (Kapoor et al 2003). Additional mutations in the α1 subunit of $GABA_A$ receptor were found in two unrelated French Canadian GGE families (Lachance-Touchette et al 2011). The Lys353delins18X and Asp219Asn mutations in *GABRA1* altered the plasma membrane expression of $GABA_A$ receptor thus affecting its cellular functioning. Additionally, a frameshift mutation in *GABRA1*, Ser326fs328X has been reported in a patient with childhood absence epilepsy (Maljevic et al 2006). The loss of α1 subunit in heterozygous *Gabra1*+/− mice leads to increased spike-wave discharges and absence-like seizures (Arain 2012).

$GABA_A$ receptors are ligand-gated (ionotropic) chloride channels and are the major inhibitory neurotransmitter receptors in mammalian brain. They mediate fast inhibitory synaptic transmission in the central nervous system. The GABA receptor is a pentameric multi-subunit complex assembled from subunits (α_{1-6}, β_{1-}

$_4$, γ_{1-3}, δ, ε, π, θ), with α1β2γ2 receptor isoform being most abundant in the brain (Macdonald and Olsen 1994, Sigel and Steinmann 2012). Mutations in α1 subunit of $GABA_A$ receptor affect its normal cellular expression and thus, disturb the inhibitory synaptic transmission. This impairment can disrupt the fine-tuned balance between excitatory and inhibitory input in neurons, leading to seizure induction by uncontrolled hyperexcitability.

1.3.2.1b EFHC1 at EJM1 (6p12-p11)

The JME locus at 6p21.2-p11 was identified by genetic analysis of a four-generation family from Los Angeles-Belize and seven multiplex families with JME (Liu et al 1995). The critical region was mapped and refined to the 6p12-p11 location (EJM1) by genotyping and recombination analysis of members of additional Mexican families (Liu et al 1996, Bai et al 2002). Mutational analyses of 18 genes in this interval excluded all except Myoclonin1/*EFHC1* (Suzuki et al 2002, Suzuki et al 2006). Five missense mutations in *EFHC1* were identified to co-segregate with epilepsy in six unrelated families. *EFHC1* encodes a 640-amino acid protein, EF-hand domain-containing protein 1, harbouring three DM10 domains and an EF-hand calcium-binding motif. EFHC1 enhances the calcium influx through $Ca_v2.3$ channel and regulates the cellular apoptosis. Mutations in this gene affect the EFHC1-induced calcium influx through the R-type calcium channel and reduce its effect on the programmed cellular death mechanism (Suzuki et al 2004). Additional *EFHC1* mutations have been reported in patients with JME (Medina et al 2008, Jara-Prado et al 2012) and JAE (Stogmann 2006) across different populations.

While the autosomal dominantly inherited single copy mutations in this gene were reported in JME patients, its homozygous mutation is associated with a severe form of epilepsy syndrome, severe intractable epilepsy of infancy, resulting in death within 18-36 months (Berger et al 2012). Although linkage analysis data from 45 mostly Mexican families mapped EJM1 to 6p12-p11, no disease-segregating *EFHC1* mutations were found in 39 of these, indicating that exonic mutations in *EFHC1* account for only a small fraction of JME cases. Additionally, three mutations reported by Suzuki et al (2004) were found relatively common in

non-Mexican populations (Greenberg and Stewart 2014). However, the occurrence of frequent and spontaneous myoclonias in heterozygous and homozygous Efhc1-null adult mice suggest that decreased function of *EFHC1* may lead to seizure susceptibility and epileptogenicity in JME patients with *EFHC1* mutations (Suzuki et al 2009).

EFHC1 is a microtubule-associated-protein (MAP) involved in cell division and neuronal migration during cortical development (de Nijs et al 2009). It associates with mitotic spindle and the midbody during mitosis and cytokinesis, respectively (de Nijs et al 2006). The *EFHC1* mutations identified in JME patients can apparently cause neuronal migration defects suggesting structural abnormalities during brain development (de Nijs et al 2012). Interestingly, a number of functional and neuroimaging studies have reported occurrence of subtle structural abnormalities in brains of JME patients, involving cortical grey matter, hippocampus, frontal lobe, etc (review by Kay and Szaflarski 2014). These pathological observations and the potential biological role/s of EFHC1 in cortical development disrupted by JME mutations, suggest that JME is a neurodevelopmental disorder and *EFHC1* mutations may cause subtle disruption of the developmental process (de Nijs et al 2013).

1.3.2.1c CACNB4 at EJM6 (2q22-q23)

The spontaneous mutation in *Cacnb4* (beta subunit gene) in *lethargic* mouse causes ataxia and seizures. It results in a 4-nucleotide insertion in a splice donor site leading to exon skipping, translational frameshift, and protein truncation (Burgess et al 1997). Inactivation of Cacnb4 in mouse results in a complex neurological condition including absence seizures and ataxia. Following this observation, the role of this gene in human epilepsies was explored by screening for mutations in *CACNB4* (calcium channel beta-4 subunit) in small families with epilepsy and ataxia, wherein a premature-termination mutation Arg482X in a patient with JME was found (Escayg et al 2000) (EJM6). Additionally, *CACNB4* mutations were detected in a German family with GGE and praxis-induced seizures (EIG9) and in a French Canadian family with episodic ataxia type 5 (EA5)

(Escayg et al 2000). The *CACNB4* gene maps to 2q22-q23 (Escayg et al 1998) and encodes for beta-4 subunit for a voltage-dependent calcium channel (VGCC). The Arg482X mutation leads to truncation of 38 amino acid residues within its C-terminus, disrupting its interaction domain for the α1 subunit. Few studies show that VGCC subunit β4 regulate gene expression via its nuclear targeting and association with regulatory protein complex (Colecraft et al 2002, Hibino et al 2003, Subramanyam et al 2009). The Arg482X mutation apparently causes conformational changes in β4 affecting its nuclear targeting, and thus results in altered gene expression of a few genes (Tadmouri et al 2012). In contrast, normal nuclear targeting of the truncated protein ($\beta_{1\text{-}481}$) was observed in different cell types such as tsA-201 cells, skeletal myotubes, and in hippocampal neurons (Etemad et al 2014). Thus, it is conflicting to conclude whether the calcium channel-dependent or nuclear function of *CACNB4* is involved in the etiology of epilepsy in humans and mouse models.

1.3.2.1d GABRD at EJM7 (1p36.33)

A homozygous Arg220His missense mutation in γ-aminobutyric acid A receptor, delta (*GABRD*) gene was identified in a patient with JME (Dibbens et al 2004). The heterozygous variation Arg220His was found in about 8.3% of the patients with genetic generalized epilepsy (EIG10) and in 4.2% of controls. As this heterozygous variation is found in the general population, its homozygosity may have contributed to the pathogenesis of JME. Besides this, the same study reported a heterozygous mutation, Glu177Ala to be associated with generalized epilepsy with febrile seizures plus. The *GABRD* gene encodes δ-subunit of the ligand-gated chloride channel for gamma-aminobutyric acid (GABA). The Arg220His mutation resulted in decreased $GABA_A$ receptor current amplitudes, which may be associated with increased neuronal excitability and predispose for seizure phenotype (Dibbens et al 2004). However, no association was observed between Arg220His variation with GGE or JME among 562 German patients (Lenzen et al 2005), excluding *GABRD* as a common susceptibility gene for JME. The absence of spontaneous seizures in *GABRD* null mice (Mihalek et al 1999) indicates that *GABRD* itself is not sufficient and may act in conjunction with other genes or environment to produce epilepsy phenotype. These studies suggest that

GABRD variants are likely to be a small part of the complex genetic architecture in contributing towards susceptibility to common epilepsies.

1.3.2.1e SLC2A1 at EIG12 (1p34)

The defective transport of glucose across the blood-brain barrier in patients with GLUT1 deficiency syndrome-1 has been associated with mutations in *SLC2A1* (solute carrier family 2, member 1; *GLUT1*, glucose transporter 1) (De Vivo et al 1991, Seidner et al 1998). Apart from severe neurological defects observed in *GLUT1* deficiency syndrome, *SLC2A1* mutations have also been reported in large and small families with less severe disorders such as paroxysomal exercise-induced dyskinesia (Suls et al 2008) and genetic generalized epilepsies (Suls et al 2009, Mullen et al 2010, Striano et al 2012) (EIG12). However, genetic heterogeneity and phenotypic variability is notable in patients with *GLUT1* mutations, varying from early onset-childhood absence epilepsy (CAE), epilepsy with myoclonic-atonic seizures to CAE evolving to JME. On screening of a cohort of 504 GGE probands from Israel and Australia, *GLUT1* mutations were found in 7 probands, contributing to about 1% of GGE (Arsov et al 2012). The functional effect of these variations varied from marked decrease in glucose transport to no effect on the protein function. These studies implicate that mutations in *GLUT1* may act as causative or susceptibility factors in GGE and other milder forms of epilepsies.

1.3.2.1f CHRNA7 at EJM2 (15q14)

At 20q13, mutations in the *CHRNA4* gene encoding the alpha-4 subunit of the neuronal nicotinic acetylcholine receptor (nAChR) were identified in rare Mendelian idiopathic epilepsy, autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE) (Steinlein et al 1995). Subsequently, markers around all nAChR genes were tested in 34 European JME families and significant evidence of linkage was obtained on chromosome 15q13–q14 close to the *CHRNA*7 gene (Elmslie et al 1997).

However, a few independent reports provided evidence against linkage of JME to the 15q14 locus. Sander et al (1999) found no evidence in favour of linkage to 15q14 in 27 JME and 30 IAE families analyzed together. Durner et al (2000) analyzed 53 families ascertained through a JME proband, but no significant evidence of linkage to chromosome 15q14 was obtained assuming genetic homogeneity and autosomal recessive mode of inheritance with 50% penetrance value. Another study supported the linkage at 15q13–14 for JME only and not with a broadly defined phenotype of GGE (Taske et al 2002) but, it failed to identify any disease-causing variant in *CHRNA7* in the 34 JME families examined earlier. Additionally, 15q13.3 microdeletions encompassing *CHRNA7* have been identified in 12 of 1,223 individuals with GGE (Helbig et al 2009), of which, six had JME.

1.3.2.1g PRICKLE1 and PRICKLE2

The role of prickle genes in epilepsy was first noted when a homozygous mutation was found in three families with progressive myoclonus epilepsy-ataxia syndrome (Bassuk et al 2008). Later, two heterozygous missense mutations each in the *PRICKLE1* and *PRICKLE2* genes were discovered in GGE/JME patients with myoclonic seizures and generalized EEG patterns (Tao et al 2011). PRICKLE proteins characterized by their PET and LIM domains, are core components to establish cell polarity during embryonic development functioning via the noncanonical WNT signaling pathway (Liu et al 2013). Prickle1 mutant mice and *Drosophila* prickle mutants exhibit a decreased seizure threshold along with generalized disorganization of the peripheral nervous system in heterozygous mutant flies. Prickle2 mutations affect the intracellular calcium release in zebrafish; and *Prickle2*$^{-/-}$ and *Prickle2*$^{+/-}$ mice show increased epileptiform discharges (Tao et al 2011). This study concludes that deregulation of the *PRICKLE* signaling pathway plays a role in causation of seizures. Its disruption may be affecting the cell polarity and positioning of neurons during development or altering the prickle-mediated calcium signaling in nervous system.

1.3.2.1h Additional whole-genome wide linkage and meta-analysis studies

Besides the studies described above, genome-wide linkage analysis on large number of multiplex families has led to identification of susceptibility loci for GGE with significant or suggestive evidence for linkage. In a collaborative study of European Consortium on the genetics of genetic generalized epilepsy, linkage analysis was conducted in 130 multiplex GGE families from the UK, France, Germany, Italy and Netherlands, with probands with CAE (n=53), JAE (n=23) and JME (n=54). Non-parametric multipoint linkage analysis provided significant evidence of a novel GGE susceptibility locus on 3q26 (Z_{NPL} = 4.19 at D3S3725) and suggestive evidence for two additional GGE loci on chromosomes 14q23 (Z_{NPL} = 3.28 at D14S63) and 2q36 (Z_{NPL} = 2.98 at D2S1371) (Sander et al 2000). Durner et al (2001) performed linkage studies on 91 multiplex GGE families and reported strong evidence for a locus common to most GGE subtypes on chromosome 18q21 (lod score 4.4 and 5.2 in multipoint and two-point analysis respectively), assuming autosomal recessive mode of inheritance. Both JME and non-JME families gave positive evidence for linkage at the 18q21 locus. Linkage was observed for the HLA region on chromosome 6 (lod score 2.5 and 4.2 in multipoint and two-point respectively) in the JME families. However, non-JME families did not show linkage to the HLA region and a suggestive evidence of linkage was detected at 5p15 and 5q14-q22 for absence epilepsies. These results supported the oligogenic model for GGE, with interactions of different combination of susceptibility loci leading to heterogeneous clinical presentations in GGE subtypes (Durner et al 2001). Another genetic linkage study involving 130 multiplex GGE families, failed to support evidence for a major GGE locus at 18q21.1 region (Sander et al 2002).

An additional genetic study was conducted which included the 126 GGE-multiplex families collected by an Australian and six European groups (Hempelmann et al 2006). To dissect out the seizure type-specific susceptibility loci, heterogeneity was decreased by conducting linkage analysis on distinct subgroups comprising 53 JME families and 73 IAE families (non-JME). The genome-wide analysis revealed linkage to two chromosomal regions: 6p12 (Z_{NPL} = 3.05 at D6S2410) and 19q13 (Z_{NPL} = 3.46 near D19S585) and evidence of a suggestive linkage at 5q34

(Z_{NPL} = 2.77 at *GABGR2*- D5S423), conferring susceptibility to myoclonic and GTCS seizures. The subgroup of IAE families (non-JME) revealed susceptibility loci mapping to 11q13 and 13q22-q31 regions, thus conferring risk for absence seizures. This study showed that distinct and shared genetic defects seem to constitute the complex genetic architecture of GGE sub-syndromes (Hempelmann et al 2006).

Most of the linked loci for GGE have not been replicated in independent set of families, reflecting the underlying genetic complexity and heterogeneity of generalized epilepsies. As these individual studies had been performed on a smaller sample size, providing a low power for detection in majority of families, they fail to reveal replicable susceptibility loci. To address this issue, EPICURE consortium performed meta-analysis of three linkage datasets comprising 379 genetic generalized epilepsies (GGE)-multiplex families of European descent (Leu et al 2012, EPICURE Consortium). These families included the families reported earlier by Sander et al (2000) and Hempelmann et al (2006) consisting of 1920 family members of whom 982 were affected by GGE [JAE/CAE (504), JME (258), EGTCS alone (205) and unclassified GGE syndromes (15)]. Under the broad trait model (all GGEs), multipoint non-parametric (NPL) and parametric HLOD analysis revealed suggestive evidence of linkage at 3p14.2 (LOD_{npl} = 2.96 at rs624755, dominant: HLOD = 2.84 at rs782728; recessive: HLOD = 3.21 at rs1374679), 5q34 (LOD_{npl} = 1.95 at rs1432881), 13q12.12 (LOD_{npl} = 2.42 at rs1008812), 19q13.42 (LOD_{npl} = 2.86 at rs9788), 1p36.22 (dominant: HLOD = 2.50 at rs1216213), and at 13q31.3 (recessive: HLOD = 2.67 at D13S1230). However, linkage analysis to dissect out the seizure type-related susceptibility genes was carried under narrow trait model for two family subgroups (235 GAE and 118 JME). The genome-wide parametric and non-parametric analysis revealed suggestive linkage at 5q34 (LODnpl = 2.31 at rs244903, dominant: HLOD = 3.23 at rs357608) and a significant linkage evidence in the chromosomal region 13q31.3 (recessive: HLOD = 5.02 at rs1332470) for absence seizures. Whereas, the parametric and nonparametric analysis for 118 JME families exhibited significant linkage at 2q34 (LOD_{npl} = 3.43 at D2S143, dominant: HLOD = 2.50 at D2S143; recessive: HLOD = 2.59 at D2S143); and a suggestive evidence of linkage at 5q34 (LOD_{npl} = 2.62 at

rs1025482, dominant: HLOD = 2.96 at rs2069347) and at 21q22.3 (dominant: HLOD 2.57 at rs2839377). Notably, some of these loci are supported by previous findings: 13q31.3 has been previously implicated for GGE and photosensitive GGE (Tauer et al 2005, Hempelmann et al 2006), 5q34 wherein a mutation in *GABRA1* causes JME in a large multi-generational family (Cossette et al 2002) and 2q34 by a report of significant linkage to JME to the region 2q33-q36 in a south Indian multi-generational family (Ratnapriya et al 2010). These meta-analysis results indicate that the risk factor at 5q34 predisposes to broad spectrum of GGE sub-syndromes, whereas susceptibility loci at 2q34 and 13q31.3 preferentially confer risk to myoclonic seizures or absence seizures, respectively (Leu et al 2012, EPICURE Consortium).

1.3.2.2 Association studies

Like many other complex phenotypes, GGE/JME has been subjected to genetic association studies in various populations (Tan, Mulley & Berkovic 2004). Many candidate genes, chosen on the basis of their physiological role or their localization in and around JME-linked loci, have been analyzed for association with JME. A few genome-wide association studies (GWAS) for epilepsy patients have been performed and results from these studies suggest that common genetic variations make a modest contribution towards epilepsy susceptibility.

Since the first locus for JME was found to be in the proximity of the HLA region on chromosome 6, initial association studies in JME addressed whether JME-locus is inside or outside the HLA region. Preliminary evidence for association between JME and alleles in the HLA region was reported in German (Durner et al 1992) and Saudi Arabian (Obeid et al 1994) population. Greenberg and colleagues (1996) reported that frequency of HLA-DR13 and HLA-DQB1 alleles were significantly higher in JME patients compared to non-JME patients, indicating that the JME locus probably lies within the HLA region, and that JME is genetically different from certain other forms of GGEs. However, other groups found no significant evidence of association of HLA alleles with JME in various populations (Moen et al 1995, Sander et al 1997, Le Hellard et al 1999).

Table 1.1: Chromosome loci and genes for GGE/JME

Chromosome location	Phenotype; OMIM	Locus/Gene/ Marker	Country/ethnic group/ancestral origin[#]	Type of study	Reference
1p36.33	GGE/JME (EJM7, EIG10)	*GABRD*	72 unrelated patients with GGE	Mutational analysis	Dibbens et al (2004)
1p36.22	GGE	Suggestive linkage	European descent families (235 with GAE and 118 with JME)	Meta-analysis of genome-wide linkage studies	Leu et al 2012 (EPICURE Consortium)
1p34	GGE (EIG12)	*SLC2A1*	Families with GGE	Mutational analysis	Suls et al 2009, Striano et al 2012, Arsov et al 2012
1q43	GGE/JME	Significant association (*CHRM3*)	3020 GGE patients and 3914 controls of European ancestry	Genome-wide association study	Steffens et al 2012 (EPICURE Consortium and EMINet Consortium)
2p16.1	GGE	*VRK2/FANCL*	2606 cases and 18990 controls (European, Asian and admixed African-American)	Meta-analysis of genome-wide association studies	ILAE Consortium on Complex Epilepsies 2014
2p16.1	GGE	Significant association (*VRK2*)	3020 GGE patients and 3914 controls of European ancestry	Genome-wide association study	Steffens et al 2012 (EPICURE Consortium and EMINet Consortium)
2q22-q23	GGE/JME (EIG9, EJM6)	*CACNB4*	90 GGE families of European descent (49 JME families)	Mutational analysis	Escayg et al 2000
2q24.3	GGE	Suggestive association (*SCN1A*)	3020 GGE patients and 3914 controls of European ancestry	Genome-wide association study	Steffens et al 2012 (EPICURE Consortium and EMINet Consortium)
2q34	JME	Significant linkage	European descent 118 families with JME	Meta-analysis of genome-wide linkage studies	Leu et al 2012 (EPICURE Consortium)

2q33–q36	JME (EJM9)	Significant linkage	4-generation family from south India	Linkage analysis	Ratnapriya et al 2010
2q36	GGE	Suggestive linkage	130 GGE multiplex families of European descent (JME, n=54)	Linkage analysis	Sander et al 2000
3p14.2	GGE	Suggestive linkage	European descent families (235 with GAE and 118 with JME)	Meta-analysis of genome-wide linkage studies	Leu et al 2012 (EPICURE Consortium)
3q13.3-q21	GGE (EIG8)	Significant linkage	3-generational south Indian family	Linkage and mutational analysis	Kapoor et al 2008
3q26/3q27.1	GGE/JME (EIG11, EJM8)	Significant linkage	130 GGE multiplex families of European descent (JME, n=54)	Linkage analysis	Sander et al 2000
4p15.1	GGE	Suggestive association	2606 cases and 18990 controls (European, Asian and admixed African-American)	Meta-analysis of genome-wide association studies	ILAE Consortium on Complex Epilepsies 2014
5q12–q14	JME (EJM4)	Significant linkage	Multi-affected three generation family from south India	Linkage analysis	Kapoor et al 2007
5q22.3	GGE	Suggestive association	2606 cases and 18990 controls (European, Asian and admixed African-American)	Meta-analysis of genome-wide association studies	ILAE Consortium on Complex Epilepsies 2014
5q34	JME (EIG13, EJM5)	*GABRA1*	Multi-affected French Canadian family; 2 unrelated French Canadian families with GGE	Linkage and mutational analysis	Cossette et al 2002; Lachance-Touchette et al 2011
5q34	GGE, JME and Absences	Suggestive linkage	European descent families (235 with GAE and 118 with JME)	Meta-analysis of genome-wide linkage studies	Leu et al 2012 (EPICURE Consortium)
5q34	GGE/JME	Suggestive linkage	126 GGE multiplex families of European descent (JME, n=53)	Linkage analysis	Hempelmann et al 2006

6p21.3	GGE/JME	Significant linkage	91 GGE multiplex families (JME, n=53)	Linkage analysis	Durner et al 2001
6p21	JME (EJM3)	*BRD2* (RING3)	JME families	Linkage and association analysis	Greenberg et al 1988, Weissbecker et al 1991, Pal et al 2003
6p12	GGE/JME	Significant linkage	126 GGE multiplex families of European descent (JME, n=53)	Linkage analysis	Hempelmann et al 2006
6p12-p11	JME (EJM1)	*EFHC1*	Hispanics (Los Angeles-Belize, Mexico), 6 Mexican families	Linkage analysis and Mutational analysis	Liu et al 1995, Liu et al 1996, Bai et al 2002, Suzuki et al 2004
8q24	GGE (EIG1)	Significant linkage	10 GGE families	Linkage analysis	Zara et al 1995
8q24	JME	Allelic association of *KCNQ3*	119 cases from south India	Association study	Vijai et al 2003b
9q32-q33	GGE (EIG3)	Suggestive linkage	A consanguineous Turkish family	Linkage analysis	Baykan et al 2004
10p11.22	GGE (EIG5)	Significant linkage	17 French-Canadian families	Linkage analysis	Kinirons et al 2008
10q25-q26	GGE/GTCS (EIG4)	Significant linkage	5 families from north India	Linkage analysis	Puranam et al 2005
11q22.2	GGE (GGE)	Suggestive association	2606 cases and 18990 controls (European, Asian and admixed African-American)	Meta-analysis of genome-wide association studies	ILAE Consortium on Complex Epilepsies 2014
13q12.12	GGE (GGE)	Suggestive linkage	European descent families (235 with GAE and 118 with JME)	Meta-analysis of genome-wide linkage studies	Leu et al 2012 (EPICURE Consortium)

13q31.3	GGE and Absences	Significant linkage	European descent 235 GAE families	Meta-analysis of genome-wide linkage studies	Leu et al 2012 (EPICURE Consortium)
13q31.3	GGE/PPR	Suggestive linkage	25 European descent families GGE and PPR	Linkage analysis	Tauer et al 2005
14q23	GGE (EIG2)	Suggestive linkage	130 GGE multiplex families of European descent (JME, n=54)	Linkage analysis	Sander et al 2000
15q11.2	GGE	Microdeletions	1234 GGE patients and 3022 controls of European ancestry, 399 GGE patients (JME, n=189)	Association study, Whole-genome oligonucleotide array CGH analysis	de Kovel et al 2010, Mefford et al 2010
15q13.3	GGE (EIG7, EJM2)	Microdeletions (*CHRNA7*)	1223 GGE patients from Europe and North America, 539 GGE cases from Australia and Europe (JME, n=183), 399 GGE patients (JME, n=189)	Case-control study/ case-control and familial segregation analysis, Whole-genome oligonucleotide array CGH analysis	Helbig et al 2009, Dibbens et al 2009, Mefford et al 2010

15q14	JME (EIG7, EJM2)	*CHRNA7*	34 European families with JME	Linkage analysis	Elmslie et al 1997
16p13.3	GGE/CAE (EIG6, ECA6)	*CACNA1H*	192 GGE patients; 240 epilepsy patients	Mutational analysis	Heron et al 2004; Heron et al 2007
16p13.11	GGE	Microdeletions	1234 GGE patients and 3022 controls of European ancestry, 399 GGE patients (JME, n=189)	Association study, Whole-genome oligonucleotide array CGH analysis	de Kovel et al 2010, Mefford et al 2010
17q21.32	GGE	Significant association (*PNPO*)	3020 GGE patients and 3914 controls of European ancestry	Genome-wide association study	Steffens et al 2012 (EPICURE Consortium and EMINet Consortium)

18q21	GGE/JME	Significant linkage	91 GGE multiplex families (JME, n=53)	Linkage analysis	Durner et al 2001
18q21	GGE	SNP haplotype association of *ME2*	156 GGE patients/108 GGE families	Case-control analysis/ family-based association	Greenberg et al 2005
19q13	GGE (GGE)	Suggestive linkage	European descent families (235 with GAE and 118 with JME)	Meta-analysis of genome-wide linkage studies	Leu et al 2012 (EPICURE Consortium)
19q13	GGE/JME	Significant linkage	126 GGE multiplex families of European descent (JME, n=53)	Linkage analysis	Hempelmann et al 2006
21q22.3	JME	Suggestive linkage	European descent 118 families with JME	Meta-analysis of genome-wide linkage studies	Leu et al 2012 (EPICURE Consortium)

#Patients and families with GGE/JME analysed in respective studies are enlisted. GGE, genetic generalized epilepsy; JME, juvenile myoclonic epilepsy; CAE, childhood absence epilepsy; GGE, genetic generalized epilepsy; PPR, photoparoxysmal response. GGE-associated rare variants in *GREM1, OR10S1*, *PPEF2, CHD1* and *PSME2* genes, identified by whole exome sequencing of 118 GGE patients [JME, n = 93] (Heinzen et al 2012) are not included in this list.

Pal et al (2003) identified highly significant linkage disequilibrium (LD) between JME and a core haplotype of five SNP and microsatellite markers with the LD peaking at *BRD2* at 6p21.3. Two JME-associated SNP variants in the promoter region of *BRD2* were detected; however, no other potentially causative variants were identified in 20 probands from families which had shown positive linkage to the locus. Subsequently, a multi-center study examining the role of *BRD2* as a risk factor for JME replicated the result in the British cohort, found suggestive evidence for its role in Ireland, but showed lack of replication in the German, Australian and Indian populations studied (Cavalleri et al 2007). Similarly, association analysis in a Dutch population identified no significant difference between the allele frequencies of SNP markers located in *BRD2* in cases and controls (de Kovel et al 2007).

In a group of 46 JME patients, including 29 individuals from families used to identify susceptibility locus at 15q14 (Elmslie et al 1997), a significant association between JME and the c.588C>T variant, located in exon 2 of the *CX36* gene was observed (Mas et al 2004). Bioinformatics analysis of the associated SNP suggested that it perturbed the expression of *CX36* by affecting exonic splicing enhancers. For the GGE-linked locus at 18q21, case-control and family-based association methods identified *ME2* (malic enzyme 2) as a gene predisposing to GGE. An increased risk to GGE was found when *ME2*-centered nine-SNP haplotype was present in the homozygous state (Greenberg et al 2005). However, a population-based association study involving 660 GGE patients and 666 controls of German descent did not exhibit association of genetic variations in *ME2* to common GGE syndromes (Lenzen et al 2005).

A two-staged genome-wide association study, including 3020 patients with GGE (1434 GAE and 1134 JME patients) and 3914 controls of European ancestry was carried out by EPICURE Consortium and EMINet Consortium to identify susceptibility alleles for common generalized epilepsies (Steffens et al 2012, EPICURE Consortium and EMINet Consortium). Joint analysis for stage-1 and -2 of the study revealed significant association at 2p16.1 (rs13026414) and at

17q21.32 (rs72823592) for genetic generalized epilepsies. The search for syndrome-related susceptibility genes discovered significant association at 2q22.3 (rs10496964) for GAE (absence epilepsies) and at 1q43 (rs12059546) for JME. The JME-associated region at 1q43 encompasses the gene encoding the M3 muscarinic acetylcholine receptor (*CHRM3*) (rs12059546).

Recently, a meta-analysis of genome-wide association studies from 12 cohorts of epilepsy patients and controls was conducted to detect risk variants for common epilepsies (ILAE Consortium on Complex Epilepsies 2014). The data obtained from published and unpublished genetic cohort studies from EPICURE, EPIGEN, Philadelphia (PA, USA), the Imperial-Liverpool-Melbourne Collaboration, GenEpa, and Hong Kong (China) were used for the meta-analysis. This study included 8696 cases and 26157 controls, belonging to European, Asian or African ancestry. Analysis in all-epilepsy category revealed significant association at 2q24.3 (*SCN1A*) and 4p15.1 (*PCDH7*). However for meta-analysis of genetic generalized epilepsy (GGE), 2606 cases and 18990 controls from eight cohorts were used. The analysis detected the genome-wide significant signal at 2p16.1 (rs2947349), located near the genes encoding vaccinia-related kinase 2 (*VRK2*) and Fanconi anaemia, complementation group L (*FANCL*). The association of 2p16.1 region in GGE cohort had been earlier reported by EPICURE Consortium (Steffens et al 2012, EPICURE Consortium and EMINet Consortium). Additionally, suggestive evidence for association with GGE was found at regions 4p15.1 (*PCDH7*), 5q22.3 (intergenic) and 11q22.2 (*MMP8*).

1.3.2.3 Massive parallel sequencing studies

Given that linkage-based candidate gene analysis and association studies have not had much success in identifying large-effect variants in majority of patients with common generalized epilepsies, comprehensive characterization of variants across the genome by next-generation sequencing (NGS) may help reveal common risk factors for epilepsies. The advancement in next-generation sequencing technologies and the reduced costs have made whole-exome sequencing (WES) or whole-genome sequencing (WGS) of individual epilepsy patients feasible.

The first reported NGS study for GGE had analyzed the exome sequences of 118 GGE patients [juvenile myoclonic epilepsy (n = 93) and absence epilepsy (n = 25)] and 242 controls of European ancestry (Heinzen et al 2012). The study employed two-stage approach involving exome sequencing of 118 GGE-affected individuals and a subsequent large-scale follow-up genotyping of identified candidate variants in a larger cohort of 878 GGE-affected subjects and 1830 controls. In total, 3897 candidate variants were subsequently genotyped in the larger follow-up cohort. No variant reached the statistical significance level of association in the study. However, a number of variants were enriched in patients than controls, notably, in genes *GREM1, OR10S1, PPEF2* and *CHD1*. A total of 1289 variants were reported exclusive to GGE patients and among these, a missense mutation (c.620C>T, p.Ala207Val) in *PSME2* was observed in five unrelated cases. Findings from this study failed to reveal a single variant that could account for more than 1% of the cases, indicating high genetic heterogeneity in generalized epilepsies. It suggests that identification of disease-causing rare variants that are present at very low frequencies needs be carried out through genome-/exome-based sequencing studies in very large sample sizes or co-segregation analyses in multiplex families (Heinzen et al 2012).

Additionally, the massive parallel sequencing technology has provided diagnostic screening method for genetically complex and heterogeneous disorders such as epilepsies. One such study reported use of targeted panels comprising 265 most relevant epilepsy genes or genes related to epilepsy phenotypes (37 GGE associated genes) to identify mutations for epilepsy. Disease causing mutations were detected in 16 out of 33 patients with different epileptic syndromes, belonging to a cohort from Germany and Switzerland (Lemke et al 2012).

1.3.2.4 Copy number variations

Copy number variations are a form of structural variation, which results in alteration of number of copies of one or more sections of DNA. They correspond to large segments of DNA being deleted (fewer than normal number) or duplicated (more than normal number); and may range from a kilobase to several megabases in size. CNVs are found on all chromosomes without any clinical significance;

however, they can be enriched in certain genomic regions known as "hotspots". CNVs are increasingly found in epilepsy patients, when often associated with developmental delay, autism spectrum disorder (ASD), intellectual disability and dysmorphic features (Sharp et al 2008, Shinawi et al 2010, Moreira et al 2014).

Besides these, CNVs have also been reported in epilepsy syndromes associated with normal intellect. Helbig and colleagues (2009) identified microdeletions at 15q13.3 in 12 out of 1,223 individuals with GGE from Europe and North America. This region was earlier implicated in 15q13.3 microdeletion syndrome in of individuals with mental retardation and epilepsy, schizophrenia, autism and other neuropsychiatric features (Sharp et al 2008, Stefansson et al 2008, Miller et al 2008). The deletions in this critical region encompass several genes such as the *CHRNA7* (a7 subunit of the nicotinergic acetylcholine receptor), which is considered a plausible candidate gene for epilepsy (Elmslie et al 1997). In another independent cohort of 539 GGE familial and sporadic GGE cases (JME, n=183) from Australia and Europe, 15q13.3 microdeletions were observed in 7 cases (3 individuals with JME) (Dibbens et al 2009). The 15q13.3 microdeletions were found *de novo* in three probands, two individuals had inherited from the unaffected parent and the transmission could not be determined in the other two probands. Though 15q13.3 microdeletions exhibit strong association with GGE in case-control studies, it does not segregate as a dominant Mendelian trait in multiplex GGE families, indicating it as a susceptibility genetic factor for epilepsies. In a group of 246 cases with 15q13.3 microdeletion syndrome, 28% of the individuals were reported to have epilepsy/seizures (Lowther et al 2014).

de Kovel et al (2010) reported a study aimed to investigate the genomic hotspot regions, previously implicated in various neuropsychiatric disorders, in order to identify the genetic factors conferring risk to GGE syndromes. A group of 1234 GGE patients from North-western Europe and 3022 controls from Germany were assessed using high-density SNP arrays; and recurrent microdeletions were found at 15q11.2 and 16p13.11. In an additional study, by using whole-genome oligonucleotide array CGH to a cohort of 517 patients with GGE or non-lesional epilepsies (JME, n=189), one or more rare CNVs were detected in 8.9% of the

affected individuals. Of these, 2.9% of the probands were found to harbour deletions in regions 15q11.2, 15q13.3, or 16p13.11 (Mefford et al 2010).

Several studies report CNVs associated with epilepsies in the absence of dysmorphic features in the same hotspot regions which were previously identified in patients with the neurocognitive phenotypes, suggesting that these common etiological genetic factors have highly variable phenotypic expressivity (Mefford 2014, Scheffer and Mefford 2014). However, the microdeletions at three genomic hotspots 15q11.2, 15q13.3 and 16p13.11 are notably associated with GGE than any other epilepsy type, though with incomplete penetrance. It indicates that the microdeletion itself is not sufficient to cause epilepsy and may act as a risk factor in the complex genetic architecture known for GGE.

1.4 Perspective

It is evident from the research findings presented in the above sections that genetic generalized epilepsies have substantial genetic component to their etiology with a complex, heterogeneous genetic architecture and phenotype-genotype correlation. These features make the identification of etiological factors for GGE quite challenging.

Over past 10 years or so, advancements in the field of human genetics and clinical diagnosis have provided a better understanding of the genetic basis of various GGE syndromes. Advanced imaging analysis techniques and EEG-triggered fMRI have provided new insights for generalized epilepsies, by enabling detailed *in vivo* studies of electrophysiology and elucidation of network abnormalities in different brain regions. Failure to elicit the history of myoclonic jerks in a clinical examination often results in a delayed diagnosis or misinterpretation of the GGE syndromes. Co-occurrence of JME with other generalized seizures, presence of EEG abnormalities in asymptomatic family members and familial clustering of different GGE syndromes indicates complexity in phenotypic characterization for this disease. Due to considerable overlap in the seizure components of common

GGE sub-syndromes, several studies tend to lump together different subtypes of GGE to find a common defining locus. Other studies advocate splitting different epilepsies on the basis of syndrome classification to identify syndrome-specific locus. However, recent meta-analysis of large datasets of linkage and association studies have employed both broad- and narrow-trait approaches to discover shared and distinct genetic factors, respectively for GGE syndromes. Such an approach has identified susceptibility loci that confer risk to a broad spectrum of GGE syndromes along with ones that preferentially predispose to myoclonic or absence seizures.

Despite using various approaches comprising family-based genetic studies as well as multi-centre linkage and association analyses of large number of GGE patients, so far only a limited number of susceptibility genes and loci have been identified, which account for a small proportion of complete genetic component of complex epilepsies. Limited success in such studies can be attributed to presence of locus- and allele- heterogeneity; and the involvement of population specific risk factors. Next-generation sequencing (NGS) methodologies have enabled whole-exome- and whole-genome- sequencing of individuals at a reasonable cost and thus, providing opportunity to identify patient-specific, disease-associated rare variants. But, such exome-based sequencing of a large number of GGE patients has apparently not yielded variants of large effects, due to high genetic heterogeneity of GGE syndromes (Heinzen et al 2012).

Due to the limitation of any single genetic approach to understand the complex genetic basis of GGE/JME, a combinatorial methodology is suggested along with improved phenotypic classification of affected individuals and their family members. Carefully clinically diagnosed affected individuals shall provide phenotypic homogeneity for seizure-specific analysis in the large datasets, thus providing verifiable common and syndrome-specific genetic signals. With this in view, combining unbiased genome-wide linkage- or association- studies with sequencing of the linked or susceptibility loci by NGS methods, might be successful in identifying the disease-linked variants for genetic generalized epilepsies.

1.5 Objectives of the present study

In this thesis, I present research work aimed towards understanding the molecular genetic basis of genetic generalized epilepsies, mainly JME. A two-step approach was employed to identify the causative genes/mutations in two multi-generational families, NIH2 and GLH5 manifesting GGE/JME, hailing from the southern parts of India. In earlier studies from our laboratory, GGE/JME-linked regions: EIG8 at 3q13.3-q21 (Kapoor et al 2008) and EJM4 at 5q12-q14 (Kapoor et al 2007), have been reported in these two families. In the present work, whole exome-based sequencing methods were used to identify the epilepsy-linked mutations in EIG8 and EJM4. These studies were conducted with the following goals: (i) To identify the epilepsy co-segregating novel/rare alleles in genes at the EIG8-3q13.3-q21 locus in NIH2, using whole-exome based sequencing approaches. And, to functionally evaluate the effect of rare variations identified in the potential epilepsy-causing gene using first line of cell-based assays (Chapter 2). (ii) To identify the epilepsy-causing genetic factor at the EJM4-5q12-q14 locus in GLH5 (Chapter 3).

Chapter 2

Exome sequencing identifies *CASR* as the epilepsy-causing gene at EIG8

The EIG8 (3q13.3-q21) locus for GGE was identified in a three-generation multi-affected epilepsy family, NIH2 and a novel variant, c.2693G>A (p.Arg898Gln) co-segregating with the disorder, was found in the CASR gene (Kapoor et al 2008). In the present study, detailed sequence analysis of a larger haplotype of about 64 Mb (3p14.2-q21) being shared by all affected members of NIH2, has been conducted by whole-exome sequencing (WES). Five novel/rare disease co-segregating variants in the EPHA6, ABI3BP, KIAA1407, IQCB1 and CASR genes were found in this critical interval. Of these, c.2693G>A (p.Arg898Gln) in CASR was predicted to be damaging. It alters an evolutionary conserved residue located in the crucial functional domain of CASR receptor. Thus, analysis of all protein-coding genes in this region allowed me to establish that c.2693G>A (p.Arg898Gln) in CASR is the causative factor in NIH2. CASR encodes an extracellular calcium-sensing receptor belonging to the family C of G-protein coupled receptors. It plays a key role in maintenance of systemic calcium homeostasis and is known to regulate several cellular processes by modulating different intracellular signaling pathways. Further, with an aim to gather additional evidence for involvement of CASR in epilepsy, sequence analysis of CASR was carried out in unrelated 480 JME/GGE patients. Five additional rare nonsynonymous mutations, p.Glu354Ala, p.Asp433His, p.Ser580Asn, p.Ile686Val and p.Ala988Val were found. The amino acid residues, Glu354, Asp433, Ser580, Ile686, Arg898 and Ala988 were found to be conserved across various species and mapped to conserved domains of the receptor, thereby suggesting their functional importance. The effect of these six epilepsy-associated nonsynonymous mutations on the CASR-regulated MAPK and PLC-IP3 pathways was evaluated in transiently transfected HEK293T cells. In these signaling assays, the mutant CASR receptors exhibited a variable leftward shift in the dose-response curves showing an enhanced responsiveness towards extracellular calcium concentrations as compared to the

wild-type receptor, thus suggesting their activating nature. Based on these observations, we propose that gain-of-function effect of these mutations may alter the CASR-regulated functions in the brain.

2.1 Introduction

A previous genetic study involving whole-genome based linkage mapping had identified a novel genetic locus, EIG8 for genetic generalized epilepsy (GGE) in a three-generation family from south India, with several of its members affected with epilepsy (Kapoor et al 2008). EIG8 (MIM: 612899) was localized to chromosome 3q13.3-q21. Genetic boundaries for the critical genomic interval were defined by D3S3675 (centromeric) and D3S1551 (telomeric), respectively. While the distal boundary of EIG8 was defined by a recombination event between D3S1267 and D3S1551 in an affected individual (II:2), its proximal boundary was defined by a recombination event between D3S3675 and D3S1278 in an unaffected individual (II:9). II:9 had no history of seizures or any neurological condition. He was 39 years of age at the time of participation in the study and was apparently well past the age of onset of JME. His *prima facie* unaffected status was considered while defining the proximal boundary of the locus. Based on these observations, Kapoor and colleagues (2008) concluded EIG8, a genomic interval of about 12 megabases (Mb) as the disease-linked locus in NIH2.

The 3q13.3-q21 interval (D3S3675 - D3S1551) harbors 78 annotated protein-coding genes (RefSeq, NCBI, build 37.3). Among these, 13 prioritized candidate genes were analyzed by Sanger sequencing, and a novel, rare heterozygous variant, c.2693G>A (p.Arg898Gln) in the extracellular calcium-sensing receptor gene *(CASR*) was identified. The variation, c.2693G>A was found in all affected members of the Family NIH2 (Figure 2.1) and was absent in 504 chromosomes of control cohort individuals (Kapoor et al 2008).

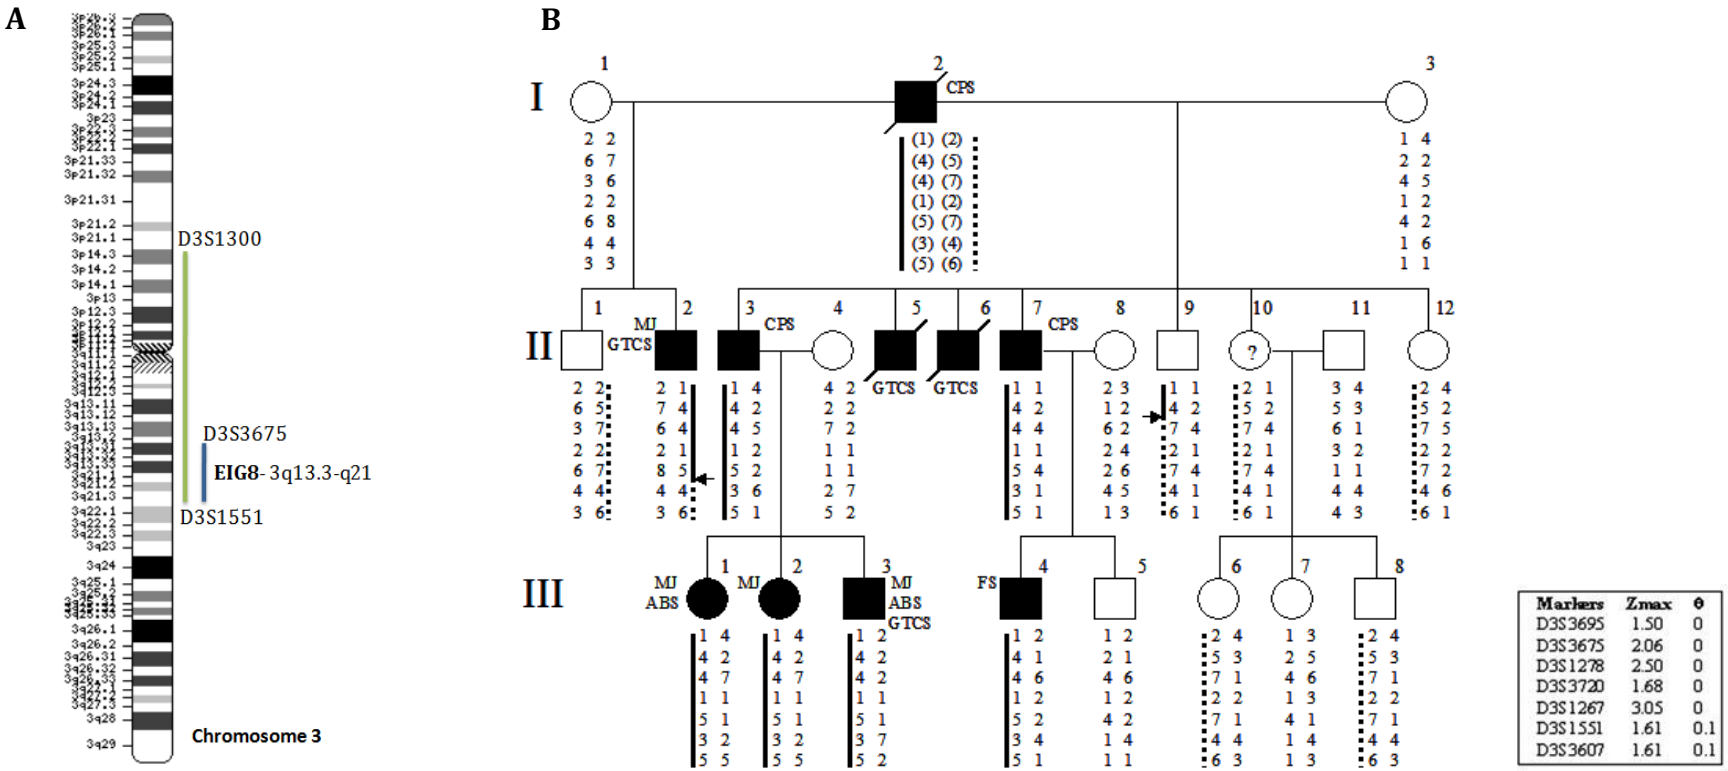

Figure 2.1: GGE-linked genetic interval in NIH2: A. Ideogram of chromosome 3 representing the location of the EIG8 locus (3q13.3-q21) on its q arm along with the extended disease-linked region (3p14.2-q21) defined by markers D3S1300 and D3S1551. **B.** Pedigree of Family NIH2 depicting the disease-linked haplotype (EIG8) shared among the affected members. Males are denoted by squares and females are denoted by circles. Filled symbols represent affected individuals and empty, unaffected ones. Haplotype consisting of 7 markers at 3q13.3-q21 is shown below the symbols. Upper and lower recombination boundaries denoting the critical region are indicated by arrows in individuals II:2 (affected) and II:9 (unaffected). Clinical features of affected subjects are indicated along with the symbols (MJ: Myoclonic jerks, GTCS: Generalized tonic-clonic seizures, CPS: Complex partial seizures, ABS: Absence seizures, FS: Febrile seizures). Adapted from Kapoor et al 2008.

At the time of publication of this report in the year 2008, majority of the genes in the critical genetic interval remained unexamined. I have revisited this study by examining all protein-coding genes (RefSeq) in the locus in two affected members of the family by using the next-generation sequencing (NGS) methods. The NGS approach permitted me to study the genes located not just in the locus delimited by boundaries in the affected-unaffected individuals (II:2 and II:9), but to examine all genes located in a larger interval (D3S1300 - D3S1551, 3p14.2-q21) defined based on recombination events in two affected individuals (II:3 and II:2) (Figure 2.1).

Further, to examine the role of *CASR* in JME/GGE, I examined its complete transcript structure in additional unrelated JME patients. The effects of identified rare nonsynonymous variants were evaluated by conducting cellular assays targeting signal transduction pathways modulated by *CASR*. Results of this study are presented in this chapter.

2.2 Materials and methods

2.2.1 Ascertainment and clinical characterization of patients and controls

The NIH2 family examined in the present study has been reported earlier, with genetic generalized epilepsy (GGE) segregating in an autosomal dominant inheritance mode (Kapoor et al 2008). Affected members of the family manifest myoclonic jerks (MJ), generalized tonic-clonic seizures (GTCS), absence seizures (AbS), complex partial seizures (CPS) and febrile seizures (FS). The family was ascertained at Department of Neurology, National Institute of Mental Health and Neurosciences (NIMHANS), Bangalore, through the proband, III:3 (Figure 2.1). From among 23 members of the family, 20 were available for the study. The family members were clinically evaluated by two neurologists and diagnosed as per the guidelines of International League against Epilepsy (ILAE) for

classification of epilepsy and epilepsy syndromes (Commission of Classification and Terminology of the International League Against Epilepsy 1989).

The proband (III:3), a 17-year old male, exhibited early morning myoclonic jerks appearing since the age of 8. He later manifested absence seizures and generalized tonic-clonic seizures (GTCS) occurring at the age of 9 and 14, respectively. His scalp electroencephalographic (EEG) recordings were abnormal, representing characteristic features of generalized epilepsy comprising generalized bursts of spikes with polyspikes. No apparent brain lesion or abnormality was observed in magnetic resonance imaging (MRI). Additional six affected individuals in the family were available for the study. Individuals III:1 and III:2, sisters of proband, had histories of myoclonic seizures, absence seizures and nocturnal myoclonic seizures. Individual II:3, father of proband and individual II:7, had histories of complex partial seizures with secondary generalization. While the EEG recordings of II:7 appeared normal, brain MRI showed presence of a calcified lesion. A few episodes of febrile seizures along with GTCS were observed in individual III:4. Individual II:2 had a history of myoclonic jerks and GTCS. Diagnosis of deceased individuals and those who could not be examined was arrived at by information provided by other members of the family. Individuals II:5 and II:6 had histories of GTCS and died in accidents during epileptic episodes. Individual I:2 was considered having CPS according to the information provided. Due to unclear clinical profile, individual II:10, was considered of unknown clinical status for genetic analysis. Individual II:12 had delayed developmental milestones with no history of seizures. The remaining members of the family were reported normal and were considered unaffected.

Additionally, about 500 JME patients were ascertained from NIMHANS, Bangalore, SCTIMST (Sree Chitra Tirunal Institute for Medical Sciences and Technology, Trivandrum) and a few epilepsy specialty clinics in south India. Clinical diagnoses of these patients were established according to the ILAE guidelines. The control cohort comprised about 250 healthy individuals from south India. These were above 20 years of age and had no apparent history of neurological disorders. The study was approved by the institutional ethics committees and ten milliliters of

peripheral blood was collected from all the subjects after obtaining a written informed consent for participation in the study. Genomic DNA was extracted using the phenol-chloroform method (Sambrook and Russel 2001).

2.2.2 Library preparation, targeted capture and exome sequencing

Whole-exome sequencing was performed on an affected parent-offspring pair (II:3 and III:2) from the family, using Agilent SureSelect All Exon 50 Mb Reagents (Agilent Technologies). Five micrograms of genomic DNA was fragmented by sonication (Bioruptor, Diagenode) to obtain fragment sizes ranging from 100 bp to 400 bp. The resulting fragmented DNA was cleaned up using Agencourt AMPure XP beads (Beckman Coulter) and checked for size distribution on a High-Sensitivity Bioanalyzer Chip (Agilent). Subsequently, genomic DNA libraries were constructed according to SureSelectXT Target Enrichment System (Agilent) for Illumina Paired-End Sequencing. DNA was subjected to a series of enzymatic reactions to repair the frayed ends, phosphorylate the fragments, add a single nucleotide A overhang and for ligation of 60 bp sequence adaptors to fragment ends. After ligation, adaptor-ligated fragments were enriched by polymerase chain reaction (PCR) amplification. The library prepared in this manner was concentrated using a vacuum concentrator (Eppendorf) and then hybridized to SureSelect™ biotinylated RNA baits at 65°C for 24-72 hours. Hybridized library fragments were isolated by magnetic capture using Dynal M-280 streptavidin coated beads (Invitrogen) followed by purification of the captured library-bead solution with AMPure XP beads. The captured library was amplified using PCR and the reaction products were purified with AMPure XP beads. The quality of the sequencing libraries was verified by capillary electrophoresis on an Agilent High Sensitivity Bioanalyzer Chip and the concentration was measured using a spectrophotometer (NanoDrop Technologies). The capture efficiency was evaluated with pre- and post-capture library samples using Brilliant II SYBR® Green QPCR Master Mix (Agilent) on Mx3005P Real-Time PCR System (Stratagene). The sequencing (72 bp paired-end reads) was carried out using an Illumina Genome Analyzer IIx (GAIIx) following the manufacturer's instructions.

Table 2.1: Summary of the next-generation sequencing data

Statistics	II:3	III:2
Data generated	19.9 Gb	20.44 Gb
Read length in bases (paired end)	72	72
Total number of reads [Percentage of high quality reads[a]]	93553724 [93.14]	96125622 [92.8]
Total number of bases [Percentage of high quality bases[b]]	6.73 Gb [94.2]	6.92 Gb [93.9]
Percentage of non-ATGC characters	0.52	0.51
Percentage of reads with non-ATGC characters	0.77	0.75
Total SureSelect probe[#] region length (whole-exome)	51.5 Mb	51.5 Mb
SureSelect probe region covered (whole-exome)	49.8 Mb	48.6 Mb
Total SureSelect probe region length (3p14.2-q21)	575 kb	575 kb
SureSelect probe region covered (3p14.2-q21)	567 kb	564 kb

2.2.3 Variant analysis

The Agilent SureSelect Human All Exon 50 Mb Kit design includes exon sequences from Consensus Coding Sequence (CCDS), NCBI Reference Sequence (RefSeq) and GENCODE annotations. The SureSelect human exome kit is devised to enrich 334,378 target exons of nearly 20,965 genes covering 51 Mb of genome. The raw sequence data (FASTQ) obtained from the sequencer was processed through an in-house analysis pipeline. The unprocessed raw reads were quality checked using SeqQC v2.1. Removal of low quality bases and trimming of adapter sequences from 3' read end was done using a customized script. Quality criteria adapted for filtering was that 70% of the bases in a sequence read should have Phred-like quality score ≥ 20, and a minimum of 50 bp read length was taken further for analysis. The high-quality processed reads were aligned to human genome reference assembly hg19 (GRCh37) using Burrows–Wheeler Aligner v0.6.0 (Li and Durbin 2009). Removal of PCR duplicates (pair of reads with identical outer coordinates) was done by Samtools v0.1.7a (Li et al 2009). Coverage statistics for aligned data were calculated using custom scripts (written in Perl) and hg19 reference gtf (gene transfer format) file (whole-exome and the 3p14.2-q21 interval). Single Nucleotide Variations (SNVs) and short insertions/deletions (Indels) were called using Samtools v0.1.7a and annotated into functional categories of nonsynonymous variants, synonymous variants, and intronic variants with SnpEff v2.0.5 (Cingolani et al 2012). These changes were further segregated as the known and novel ones, based on their presence/absence in the Database of Single Nucleotide Polymorphisms (dbSNP) 131. The shortlisted variations were then checked in the updated release of dbSNP and 1000 Genomes.

The gene variants located in the critical region (3p14.2-q21) were considered for further analysis and in order to avoid missing any potentially 'meaningful' variants, all novel heterozygous variations and indels up to 3x read depth were examined and verified. Additionally, there were about 100 exons in different genes in this 64 Mb region, which were uncovered or had low coverage in the exome sequencing data, due to their absence from the design of the Agilent capture probes. To examine these low coverage exons or gaps, each of them were PCR amplified, Sanger sequenced and examined.

2.2.4 Validation of novel/rare variants (NGS-chr 3 region)

All novel and rare variants identified in the 3p14.2-q21 region by NGS were verified by Sanger sequencing. Primers for the variant-harboring exon/amplicons and missing exons were designed using Primer 3 (Untergrasser et al 2012, Koressaar et al 2007) and Oligo Calc (Kibbe 2007), and obtained from Sigma-Aldrich (Appendix I A2.2). Genomic DNA (100 ng) was amplified by PCR in a reaction volume of 20 µl containing 0.25 µM of each forward and reverse primer, 800 µM of dNTPs (200 µM of each dNTP), 1X reaction buffer (50 mM KCl, 20 mM Tris-HCl pH 8.4), 1.5 mM $MgCl_2$ and 1 U of *Taq* polymerase (Invitrogen, Life Technologies). Amplifications were performed using a GeneAmp® 9700 (Applied Biosystems, Life Technologies) at conditions: initial denaturation at 94°C for 10 minutes, 30-40 cycles of denaturation of 94°C for 30 seconds, annealing at 53-64°C for 30 seconds and extension 72°C for 30 seconds and a final extension at 72°C for 10 minutes. Amplification products were verified by 1.5% agarose/TAE/EtBr gel electrophoresis. These products were purified using the 96-well Multiscreen® Filter plates (Millipore) and eluted in 20 µl of deionized water.

DNA sequencing was performed by cycle sequencing using 1 µl Ready Reaction Mix of the BigDye Terminator Cycle Sequencing kit v3.0 (Applied Biosystems) containing fluorescent-labeled dideoxy-terminators, 2-3 µl (50-100 ng) of purified PCR product and 0.4 µM of primer in a 20 µl reaction volume. The cycle sequencing was performed at following conditions: initial denaturation (96°C, 1 minute) followed by 25 cycles of denaturation (96°C, 10 seconds), annealing (50°C, 5 seconds) and extension (60°C, 4 minutes). After cycle sequencing, the products were purified by ethanol precipitation. The pellet was dissolved in 10 µl of Hi-Di formamide (Applied Biosystems), denatured at 95°C for 5 minutes and analyzed on an automated 48-capillary sequencer (ABI 3730 Genetic analyzer, Applied Biosystems). The sequences obtained were aligned to the respective reference gene sequence (RefSeq database, NCBI) using SeqMan II v5.01 (DNASTAR Inc.). The variants common to the NGS-sequenced samples (II:3 and III:2) were checked

for their presence/absence in other family members of NIH2. The disease-segregating alleles were further examined in the control cohort.

2.2.5 Bioinformatics analysis of novel/rare disease-segregating variants (NGS-chr 3 region)

To predict the plausible effect of the novel missense variations in *CASR* and *KIAA1407*, on the structure and function of their respective proteins, PolyPhen-2 (Adzhubei et al 2010), Sorting Intolerant from Tolerant (SIFT) (Ng et al 2003), Align GVGD (Tavtigian et al 2006), Screening for Non-Acceptable Polymorphisms (SNAP) (Bromberg and Rost 2007) and PMut (Ferrer-Costa et al 2005) were used. The effects of non-coding variants in *EPHA6*, *ABI3BP* and *IQCB1* on the splicing mechanism and translation start process were assessed using *in silico* tools: NetStart 1.0 (Pedersen and Nielsen 1997) NetGene2 (Brunak et al 1991), Human Splicing Finder v2.4.1 (Desmet et al 2009), Alternative Splice Site Predictor (ASSP) (Wang and Marín 2006) and NNSPLICE0.9v (Reese et al 1997). Multiple sequence alignments of DNA or protein sequences from different organisms were carried out by Clustal Omega (Sievers et al 2011). The respective reference nucleotide or protein sequence of each organism was taken from NCBI (GenBank) (Appendix I A2.3).

2.2.6 Mutational analysis of CASR

Complete transcript structure of *CASR* comprising of its exons and their flanking intronic regions (NM_000388.3) were screened by Sanger sequencing in apparently unrelated 480 JME patients and 252 control individuals. Primer pairs for amplification were designed using online software tools, Primer 3 and Oligo Calc (Appendix I A2.2). PCR amplification for individual fragments was performed at their respective standardized conditions on a GeneAmp® 9700. The conditions used were: initial denaturation at 94°C for 5 minutes, followed by 35-40 cycles of denaturation at 94°C for 30 seconds, annealing at 55-60°C for 30 seconds and extension at 72°C for 30 seconds, followed by final extension at 72°C for 10 minutes. PCR amplification was carried out using 100 ng of genomic DNA, 0.25 µM of each forward and reverse primer, 800 µM of dNTPs (200 µM of each dNTP),

1.5 mM $MgCl_2$, 1X reaction buffer (50 mM KCl, 20 mM Tris-HCl pH 8.4) and 1 U of *Taq* DNA polymerase in a reaction volume of 20 µl. The amplified products were verified by gel electrophoresis using 1.5% agarose/TAE/EtBr. These were then purified using 96-well Multiscreen® Filter plates according to the manufacturer's protocol and eluted in 20 µl of deionized water. DNA sequencing was performed as described earlier and products were analyzed on an ABI 3730 Genetic analyzer. The sequences were compared to the *CASR* reference sequence (NM_000388.3), available at the RefSeq database, NCBI and sequence variants were identified using SeqMan II v5.01.

2.2.7 Bioinformatics analysis of CASR mutations

Potential pathogenicity of the rare nonsynonymous variants identified in *CASR*, was evaluated using bioinformatics tools: Sorting Intolerant from Tolerant (SIFT), Polyphen-2, AlignGVGD and Mutation Assessor (Reva et al 2011). The protein sequence of CASR (NP_000379.2) from NCBI was used as the input file for these tools. To observe the conservation status of the altered amino acid residues across various organisms of different genera, alignments of the CASR protein sequences were performed using Clustal Omega. The CASR reference protein sequence of each organism used for sequence alignment was obtained from NCBI (Appendix I A2.3).

2.2.8 Cloning of CASR cDNA and site-directed mutagenesis

CASR cDNA (NM_000388.3, CCDS 3010.1) encoding the 1078 amino acids receptor, was PCR amplified from human adult brain cDNA (Marathon-Ready™ cDNA, Clontech). For amplification, gene-specific primers 5'-TGGAGAGCTAGCG CCACCATGGCATTTTATAGCTGC-3' (forward) and 5'-CTCTCTGCATCTCGAGTAG CCCAGTCTTCTCCTTCC-3' (reverse) were used, harboring the NheI and XhoI restriction enzyme sites incorporated to facilitate cloning. Amplification was performed using 1.5 ng of whole brain cDNA as template with 5 pmol of each primer and 2% DMSO. The amplified product was purified and cloned into the pcDNA3.1 (+) mammalian expression vector (Invitrogen) as a NheI-XhoI fragment (adapted from Kapoor A, PhD thesis 2006). The sequence of the cDNA insert was

verified by Sanger sequencing using cDNA insert primers (Appendix I A2.2). The *CASR* cDNA constructs with mutations incorporated, were generated by site-directed mutagenesis, carried out using QuikChange® II XL mutagenesis reagents (Stratagene). The mutagenic oligonucleotide primer pairs (Appendix I A2.2) were designed to incorporate point mutations in the cDNA and subsequently used for amplification of parental *CASR* pcDNA3.1 vector by Pfu Turbo DNA polymerase. After digestion of the parental DNA construct with DpnI for one hour at 37°C, E.coli XL-10 cells were transformed with 2-5 µl of the reaction containing amplified DNA with incorporated nucleotide substitution. The plasmid DNA was isolated from bacterial culture of insert positive clones using QIAprep® Spin Miniprep Kit (Qiagen). The transformants were screened by sequencing of the mutation-harboring cDNA in the plasmid, using the BigDye Terminator Cycle Sequencing reagents on an ABI3730 Genetic Analyzer. The obtained cDNA insert sequences were compared to *CASR* reference sequence (NM_000388.3, CCDS 3010.1) using Seqman II v5.01.

2.2.9 Cell culture and transient transfections

Human embryonic kidney (HEK293T) cells were grown in Ca^{2+}-free high glucose Dulbecco's Modified Eagle Medium (DMEM, Invitrogen) supplemented with 10% heat inactivated fetal bovine serum (FBS, Sigma), 2mM L-glutamine (Sigma) and antibiotics (100 U/ml penicillin and 10 mg/ml streptomycin, Sigma) at 37°C in humidified atmosphere of 5% CO_2. For signaling assays, HEK293T cells were sub-cultured in 6-well or 24-well plates (BD biosciences). Next day, the culture medium was replaced with the antibiotic- and serum-free Ca^{2+}-free DMEM for transient transfection with different vector constructs using Lipofactamine® 2000 transfection reagent (Invitrogen).

2.2.10 MAPK (mitogen-activated protein kinase) assay

The effect of missense mutations on functional aspects of CASR regulated MAPK signaling was evaluated by using PathDetect® *in vivo* Signal Transduction Pathway Elk-1 *trans*-Reporting System (Stratagene). This cell-based assay measured the activity of Elk-1, an ETS domain containing transcription factor targeted by MAPK

pathways in response to various extracellular calcium concentrations. HEK293T cells were grown in Ca^{2+}-free DMEM in 6-well plates. At 70% confluence, cells were transiently co-transfected with 1 μg of wild-type (WT)- or mutant- CASR-pcDNA3.1 or empty vector (pcDNA3.1+), 1 μg of pFR-Luc reporter plasmid (Stratagene), 50 ng of pFA2-Elk1 plasmid (Stratagene) and 50 ng of pCMVβ-galactosidase plasmid (transfection control plasmid) (Clontech) using Lipofectamine™ 2000 (Invitrogen) in serum-free DMEM. Six hours post-transfection, the medium was replaced to serum supplemented DMEM. The following day, the cells were serum starved in DMEM with 0.5 mM $CaCl_2$ for 8 hours and then replaced with media containing different concentrations of $CaCl_2$ (0, 0.5, 1, 2, 3, 4, 5, 6, 8, 10, 12 and 15 mM) for 16 hours. The cells were washed with 1X phosphate-buffered saline (PBS) and lysed using 200 μl of 1X Reporter Lysis Buffer (RLB, Promega) on ice. Post lysis, the cells were centrifuged at 15,000 rpm for 2 minutes at 4°C and the supernatant was collected for activity measurements. Luciferase activity was measured on a Luminometer (Berthold) using 2 μl of cell lysate and 20 μl luciferase assay reagent (1:10) (Luciferase Assay System, Promega). β-galactosidase enzyme activity was measured in a 96-well microplate reader (Molecular Devices) using 50 μl of diluted cell lysate (5 μl cell lysate and 45 μl of 1X RLB) and 20 μl of Assay 2X Buffer (Promega) in each well. The assay mixture was incubated at 37°C for 15-20 minutes (appearance of yellow colour) and the activity was stopped using 50 μl of 1 M Na_2CO_3. Then, the absorbance values were measured at 420 nm. Luciferase activity was normalized to the β-galactosidase reading for each cell lysate.

2.2.11 Inositol monophosphate (IP1) assay

The response of cultured HEK293T cells transiently expressing wild-type or mutant CASR to various extracellular Ca^{2+} was assessed by measuring intracellular IP1 (Inositol 1-phosphate) accumulation using an Elisa-based method (IP-One Cell Elisa Assay Kit, CISBIO Bioassays). HEK293T were sub-cultured in Ca^{2+}-free DMEM in 24-well plates. Next day, they are transfected with 0.5 μg of WT- or mutant- CASR-pcDNA3.1 or empty vector (pcDNA3.1+) along with 25 ng of pCMV β-galactosidase plasmid (transfection control plasmid) using Lipofectamine® 2000

(Invitrogen) in serum-free medium. Forty-eight hours post-transfection, DMEM was removed and cells were treated with 200 µl of Stimulation Buffer (10 mM Hepes, 0.5 mM $MgCl_2$, 4.2 mM KCl, 146 mM NaCl, 5.5 mM Glucose, 50 mM LiCl pH=7.4) containing different $CaCl_2$ concentrations (0, 2, 3, 4, 5, 6, 8, 10 mM) for 1 hour at 37°C and 5% CO_2. Following treatment, cells were lysed for 30 minutes at 37°C with 50 µl of 2.5% IP-One ELISA Kit Lysis Reagent and the assay was performed according to the manufacturer's guidelines. The ODs were determined at 450 nm (with optical correction at 620 nm) on Varioskan™ Flash (Thermo Scientific). IP-One ELISA Kit determines the accumulation of intracellular IP1 based on competition between free IP1 and IP1-HRP (Horse-Radish Peroxidase) conjugate, for binding sites on an anti-IP1 monoclonal antibody. The IP1 accumulation for each experiment was calculated as percentage inhibition of IP1-HRP binding = [1 - IP1-HRP binding in stimulated cells/IP1-HRP binding in unstimulated cells] X 100. Therefore, IP1 accumulation in wild-type or mutant CASR transfected cells in response to increasing Ca^{2+} concentration was expressed as percentage inhibition of IP1-HRP binding.

2.2.12 Statistical data analysis

For MAPK assay, the signaling activity represented by relative luciferase units for wild-type and mutant receptors was plotted as mean ± SEM of three independent experiments. In IP-One ELISA based assay, accumulation of IP1 (percentage inhibition of IP1- HRP binding by IP1) for each receptor was represented as mean ± SEM of six independent experiments. The curve fitting for dose-response values were performed using non-linear regression in Prism 5 (GraphPad software, Inc) and EC_{50} (the agonist concentration giving one-half of the maximal response) was calculated using Boltzmann equation in Origin 6.1 (OriginLab Corporation). The mean EC_{50} values for wild type or each mutant CASR receptor in response to increasing concentrations of Ca^{2+} was calculated from the EC_{50} values for all of the individual experiments and is expressed with the standard error of the mean (SEM). The bar graphs to compare signaling response values of mutant receptors to wild-type CASR at three calcium concentrations were plotted using GraphPad Prism 5. Statistical analyses were performed using unpaired Student's t test (GraphPad Prism 5), and P values < 0.05 (two-tailed) were regarded as significant.

2.3 Results

2.3.1 Exome sequencing and variant analysis

Pursuing the previous linkage and candidate gene study regarding the EIG8 locus (Kapoor et al 2008), I utilized the next-generation sequencing methods to identify if there are additional gene variants which may be causative beyond the proposal of c.2693G>A (p.Arg898Gln) in *CASR* for GGE. An extended haplotype of 64 Mb shared by all affected individuals in the family was considered for analysis. And this disease-linked critical interval harbors 214 well annotated protein-coding genes (RefSeq, NCBI, build 37.3).

Whole-exome sequencing (WES) was performed on genomic DNA from an affected parent-offspring pair (II:3 and III:2). Individuals II:3 and III:2 share the GGE-linked haplotype between D3S1300 and D3S1551. Sequencing libraries from both samples were prepared using SureSelect target enrichment system (Agilent SureSelect Human All Exon 50MB kit) and sequenced as 72 bp paired-end reads on Illumina GAIIx platform. A total of 18 Gb of raw sequence data with 93-96 million reads was obtained per sample. After removal of low quality bases and adaptor sequences, about 92% sequence reads were found to be of high-quality (≥70% bases in a read with Phred-like quality score ≥20) (Table 2.1). The sequence reads were aligned to the human genome reference (hg19) using BWA (v0.6.0). The target sequence length of SureSelect probes covers about 51 Mb of exonic region of the human genome. On average, 95% of the SureSelect probe targeted region was covered at least once. For the whole-exome probe region, 10-fold coverage was 80-86%; and 71-78% of the probe region was covered by at least 20 reads (Table 2.2). For further analysis, we focused on variations in genes of the extended GGE-linked interval (64 Mb) on chromosome 3 between the markers D3S1300 and D3S1551 (3p14.2-q21). The SureSelect probes cover about 575 kb of exonic region in this interval. The intended probe region had an average read depth of 83x with nearly 90% of the region covered at least 20 times (Table 2.2).

Table 2.3: Novel/rare variants observed in the 3p14.2-q21 region from both NGS-ed samples (II:3 and III:2)

[a]Genomic position of the nucleotide base on chromosome 3 (chr 3) (GRCh37, NCBI). [b]Nomenclature of variants in introns or untranslated regions (5'UTR and 3'UTR) is with respect to first base of the corresponding cDNA. The position of variations is numbered according to cDNA of the longest protein-coding transcript. [c]Variants present in all affected members of NIH2 were considered positive for disease co-segregation. [d]The novel/rare variants were checked in updated release of dbSNP and 1000 Genomes; and the variants present at minor allele frequency (MAF) ≤ 0.005 in the databases were included. The five new variants represented in bold segregated with clinical phenotype in NIH2 and were found absent in the control cohort individuals (n=96 for intronic variations and n=250 for nonsynonymous variations).

The coding exons along with their 100 bp flanking intronic sequence were considered for identification of rare variants segregating with epilepsy phenotype in NIH2. Given the autosomal dominant mode of inheritance of disease in the family, heterozygous variants were selected. We identified 24 novel/rare variants, of which, 9 were found to co-segregate with epilepsy in the family (Table 2.3; Figure 2.3). The allele frequencies of these 9 variations were examined in the control cohort and databases. Five variants: c.1895-76T>C in *EPHA6*, c.1009+83A>G in *ABI3BP*, c.614G>A in *KIAA1407*, c.-12-46T>C in *IQCB1* and c.2693G>A in *CASR* were found to be absent among controls examined (Table 2.3). The common variants or polymorphisms identified in the region are enlisted in Appendix I A2.1.

2.3.2 Predictive effect of novel/rare disease-segregating variants (NGS-chr 3 region)

The five new variations were studied for their predictive pathogenicity and evolutionary conservation across various organisms using multiple *in silico* tools. These variants were located in the following genes: *EPHA6* (MIM: 600066), *ABI3BP* (MIM: 606279), *KIAA1407*, *IQCB1* (MIM: 609237) and *CASR* (MIM: 601199). The intronic variants c.1895-76T>C in *EPHA6* and c.1009+83A>G in *ABI3BP* were predicted to have no apparent effect on the splicing regulation of the neighboring exons (Table 2.4). The c.-12-46T>C variation in *IQCB1* is present in the intron between two non-coding exons and lies 46 bases upstream of the translation start site. According to the predictive tools, it neither affects the splicing of non-coding exons nor the translation start site. Two variations that lead to missense substitutions were, c.614G>A (p.Arg205Lys) in *KIAA1407* and c.2693G>A (p.Arg898Gln) in *CASR* (Figure 2.2). The p.Arg205Lys in KIAA1407 alters arginine, a positively charged amino acid residue to a basic amino acid residue, lysine and was therefore predicted to have a neutral effect to the protein. However, p.Arg898Gln substitution in CASR alters a positively charged amino acid to a neutral amino acid and is predicted to have damaging functional consequence to the protein (SIFT score- 0.01; Polyphen-2 score-0.68, Align-GVGD- C35) (Table 2.4).

Table 2.4: Bioinformatics analysis of the five novel disease co-segregating variants (3p14.2-q21)

The effect of missense substitutions was predicted using SIFT, Polyphen-2, SNAP, PMut and Align GVGD. Tools such as NNSPLICE, HSF, NetGene and ASSP evaluated the effect of intronic variants on splicing of the flanking exons. *NetStart 1.0 examined the effect of the intronic variant, c.-12-46T>C in *IQCB1*, present between two non-coding exons. §DNA or protein sequence alignment was done using Clustal Omega (found conserved in out of those examined). #In AlignGVGD, Class C65 to C25 ranges from most to least likely to interfere in protein function.

Figure 2.2: The c.2693 G>A (p.Arg898Gln) mutation in *CASR*: **A.** Alignment of the exome sequence reads against human genome reference sequence as viewed in tview of samtools v0.1.7a. The snapshot here shows the reads in forward (caps) and reverse (no caps) strands indicating the heterozygous G>A variation at g.122003494 in *CASR*. The dot and comma represent the matched reference allele and alphabet shows the variant allele. **B.** Electropherograms of sequence with wild-type (G/G) and variant allele (G/A) for the c.2693G>A variation in *CASR*. The arrow indicates the nucleotide showing heterozygous variation shown by presence of two peaks. **C.** Multiple protein sequence alignment of CASR from 26 species by Clustal Omega. The arginine (R) 898 is highlighted in blue.

The conservation of nucleotide residue or amino acid residue was observed by multi-species DNA/protein sequence alignment using Clustal Omega. The nucleotide positions c.1895-76T in *EPHA6*, c.1009+83A in *ABI3BP* and c.-12-46T in *IQCB1* were found to be variable. The amino acid residue p.Arg205 in KIAA1407 was found to be moderately conserved in other organisms. But, the amino acid residue Arg898 in CASR was found to be highly conserved in species as distantly related as humans and zebrafish, indicating its high functional significance (Figure 2.2).

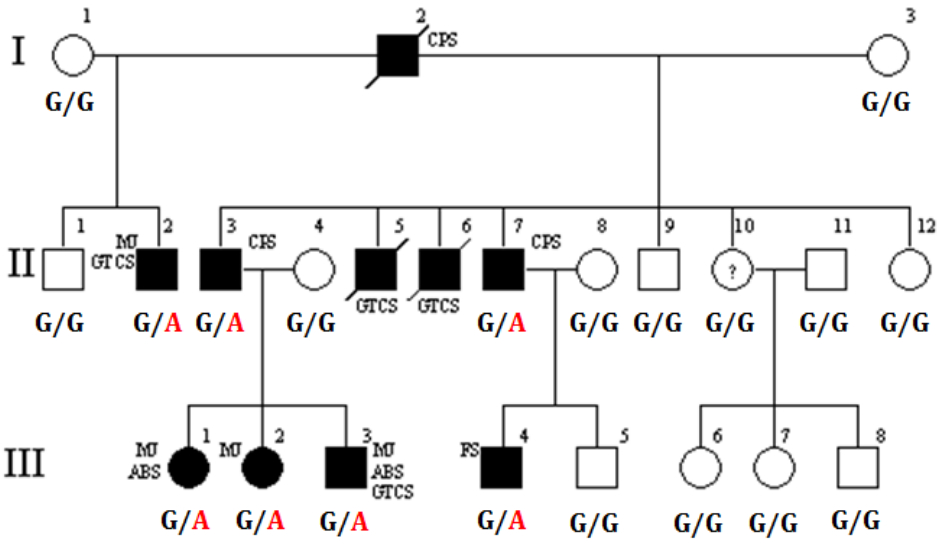

Figure 2.3: Segregation analysis of *CASR* variation, c.2693G>A in NIH2: The genotypes (G/G or G/A) for c.2693 nucleotide position are written below the respective symbols representing family members. The wild-type genotype is G/G and the variant allele (A) present in heterozygous state is shown as G/A (red).

Table 2.5: Novel/rare *CASR* variants observed in 480 JME patients

[a]Genomic position of the nucleotide base on chromosome 3 (chr 3) (GRCh37, NCBI). [b]The nucleotide and amino acid residue position of the variations in *CASR* is according to its shorter transcript encoding for receptor of 1078 amino acids (NM_000388.3, NP_000379.2). [c]ECD: extracellular domain, TMD: transmembrane domain, ICD: intracellular domain. [d]Minor allele frequencies (MAF) is calculated in 252 control individuals. [e]Variations were checked for their presence in updated release of dbSNP and 1000 Genomes; and variants present at minor allele frequency (MAF) ≤ 0.005 in the databases were included. [f]The CASR mutations p.Glu354Ala, p.Ile686Val, p.Arg898Gln and p.Ala988Val were reported for epilepsy in our earlier study (Kapoor et al 2008). The p.Asp433His has been reported for chronic pancreatitis by another study (Murugaian et al 2008). These reported mutations are present in the Human Genome Mutation Database (HGMD) and are designated by CM_ID.

2.3.3 Rare CASR variants in JME patients

To examine the potential contribution of the *CASR* gene for predisposition to epilepsy, all exons of the gene were sequenced in a set of 480 JME patients and 252 individuals of control cohort. The sequences obtained were compared to the *CASR* reference sequence (NM_000388.3, RefSeq, NCBI). Six rare nonsynonymous variations altering highly conserved residues in the receptor were found. These were: c.1061A>C (p.Glu354Ala), c.1297G>C (p.Asp433His), c.1739G>A (p.Ser580Asn), c.2056A>G (p.Ile686Val), c.2693G>A (p.Arg898Gln) and c.2963C>T (p.Ala988Val) (Table 2.5, Figure 2.4)). These rare alleles were either absent or present with minor allele frequencies (MAF) ≤ 0.005 in 504 control chromosomes examined, dbSNP and 1000 Genomes database. The mutations, p.Glu354Ala, p.Ile686Val, p.Arg898Gln and p.Ala988Val were reported earlier in epilepsy patients (Kapoor et al 2008). The p.Asp433His allele was reported in a patient with tropical chronic pancreatitis (Murugaian et al 2008). These mutations are present in the databases with Human genome Mutation Database (HGMD) ID.

The mutation detected in NIH2, c.2693G>A (p.Arg898Gln) was found in one additional JME patient. The mutations, p.Asp433His, p.Ile686Val and p.Ala988Val variants were observed in more than one unrelated JME affected individuals (Table 2.6). A few synonymous substitutions and rare variants located in the 5'UTR and intronic regions of the gene were also found (Table 2.5) along with certain common polymorphisms (Appendix I A2.4). I have considered the novel/rare nonsynonymous variations for further analysis.

Table 2.6: Clinical characteristics of JME patients harboring CASR mutation

CASR mutation	Gender	Age of onset (years)	Seizure types	EEG	Medication

Figure 2.4: *CASR* mutations associated with epilepsy: A. Electropherograms showing DNA sequence of the respective wild-type (WT) (upper panel) and the mutation (lower panel) from the genomic DNA. The presence of two peaks at one nucleotide position indicates the heterozygous variation (marked with red*) for each mutation (p.Glu354Ala, p.Asp433His, p.Ser580Asn, p.Ile686Val, p.Arg898Gln and p.Ala988Val). **B**. Alignment of CASR protein sequence from various organisms by Clustal Omega, showing only the region near the location of mutated amino acid residue. The wild-type amino acid residue for each mutation is highlighted in blue (E354, D433, S580, I686, R898 and A988).

2.3.4 Predictive effect of CASR mutations

According to the *in silico* tools used, the six missense mutations (p.Glu354Ala, p.Asp433His, p.Ser580Asn, p.Ile686Val, p.Arg898Gln, p.Ala988Val) identified in the CASR receptor have benign to damaging functional effect on the protein (Table 2.7). The multiple sequence alignment of human CASR protein with its orthologs by Clustal Omega showed that the amino acid residues Glu354, Asp433, Ser580, Ile686, Arg898, and Ala988 are highly conserved (Figure 2.4). This suggests that these amino acid residues have structural and functional biological importance.

Table 2.7: Bioinformatics analysis of CASR nonsynonymous mutations

CASR mutation	SIFT	Polyphen-2[a]	Align GVGD[b]	Mutation assessor[c]	Evolutionary conservation
Glu354Ala	Tolerated (0.33)	Probably damaging (0.992)	C65 (106.71)	Medium FI (2.305)	26/26
Asp433His	Tolerated (0.1)	Probably damaging (0.967)	C65 (81.24)	Medium FI (2.655)	26/26
Ser580Asn	Tolerated (0.33)	Probably damaging (0.997)	C65 (46.24)	Low FI (1.515)	26/26
Ile686Val	Tolerated (0.18)	Benign (0.012)	C25 (28.68)	Low FI (0.985)	26/26
Arg898Gln	Damaging (0.01)	Possibly damaging (0.555)	C35 (42.81)	Medium FI (2.515)	25/26
Ala988Val	Tolerated (0.14)	Benign (0.005)	C65 (65.28)	Medium FI (1.905)	25/26

2.3.5 Effect of CASR mutations on MAPK pathway

CASR plays an important role in maintenance of calcium ion homeostasis by sensing its extracellular levels and responding to its changes via regulation of different downstream signaling pathways such as MAPK (mitogen-activated protein kinase), Phospholipase C (PLC) - mediated inositol triphosphate (IP3) formation, etc. (Ward 2004, Conigrave and Ward 2013). The effect of mutations in CASR receptor, towards response to changes in extracellular calcium concentrations, was studied using PathDetect *trans*-reporting system to measure the activity of Elk-1. The Elk-1 belongs to Ets oncogene family of transcription factors containing a highly conserved DNA-binding domain (Ets domain) and is targeted by MAPK pathways (Janknecht et al 1993, Besnard 2011). In this system, the activation domain of Elk-1 is expressed as a fusion *trans*-activator protein and is phosphorylated and activated by MAPK. This activity regulates the expression of luciferase gene, which in turn, reflects the activation status of the signaling events downstream of CASR in response extracellular calcium (Figure 2.5).

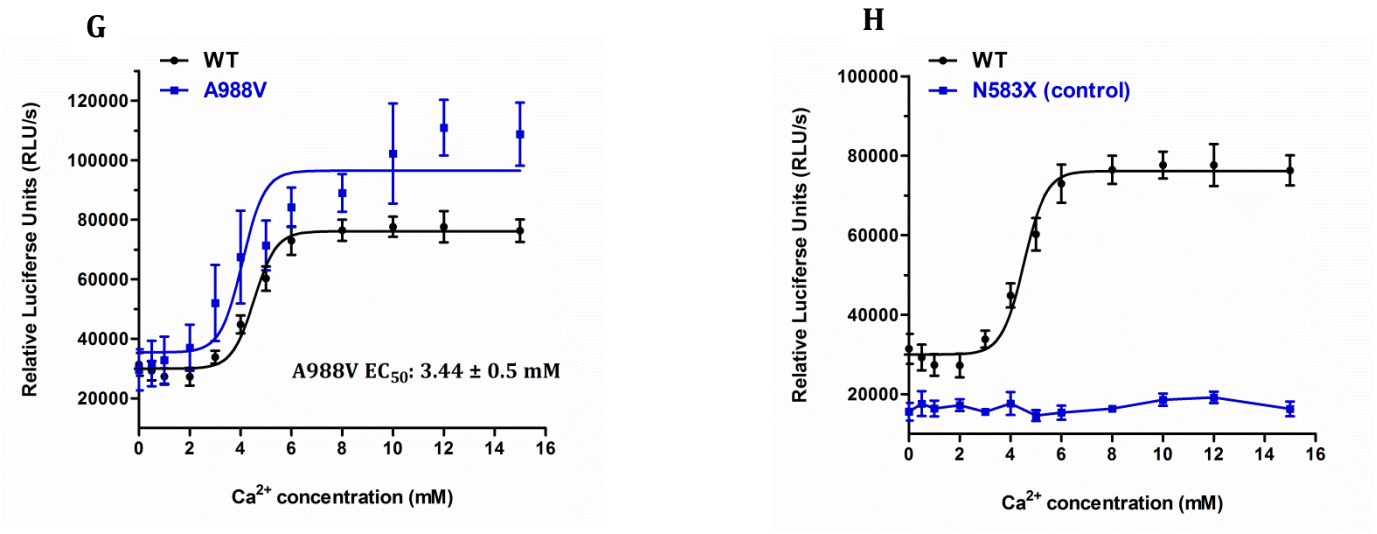

Figure 2.6: Cell signaling (MAPK pathway) of wild-type and mutant CASR receptors in transfected HEK293T cells: Extracellular calcium-evoked increase in MAPK activity in HEK293T cells transiently transfected with control (pcDNA3.1 vector or CASR-N583X), wild-type (WT) or mutation harbouring (E354A, D433H, S580N, I686V, R898Q, A988V) *CASR* cDNA constructs along with vectors of MAPK *trans*-reporting system. In each plot, activity response of WT is presented in black, whereas, of mutant receptor is shown in blue. The basal level signaling activity in cells with control vectors is shown in plots A and H. The dose-response curves of signaling response by mutant receptors is presented in graphs B-G. Values shown here are mean of readings from three independent experiments and are plotted as mean ± SEM.

With exponentially increasing activity in the 3-6 mM range of Ca^{2+} concentration and saturation at higher calcium levels, the signaling activity of CASR across different extracellular Ca^{2+} concentrations (0, 0.5, 1, 2, 3, 4, 5, 6, 8, 10, 12 and 15 mM) generated a sigmoidal dose-response curve. In cultured HEK293T cells, the wild-type (WT) CASR receptor showed a half-maximal response (EC50) at 4.31 ± 0.13 mM (mean ± SEM). The signaling response by p.Glu354Ala, p.Asp433His, p.Ser580Asn, p.Ile686Val, p.Arg898Gln and p.Ala988Val mutant receptors exhibited a variable leftward shift in the dose-response curves (Figure 2.6). The EC50 values of mutant receptors p.Ile686Val: 3.52± 0.35 mM, p.Arg898Gln: 3.72 ± 0.27 mM and p.Ala988Val: 3.44 ± 0.5 mM were significantly lower than that of wild-type ($p < 0.05$). But, the EC50 values for p.Glu354Ala: 3.76 ± 0.33 mM, p.Asp433His: 4.29 ± 0.1 mM, p.Ser580Asn: 3.87 ± 0.15 mM did not differ significantly from that of the wild-type CASR. The vector (pcDNA3.1) and control (CASR-Asn583X pcDNA3.1) transfected cells exhibited basal level activity in response to increasing extracellular Ca^{2+} concentrations.

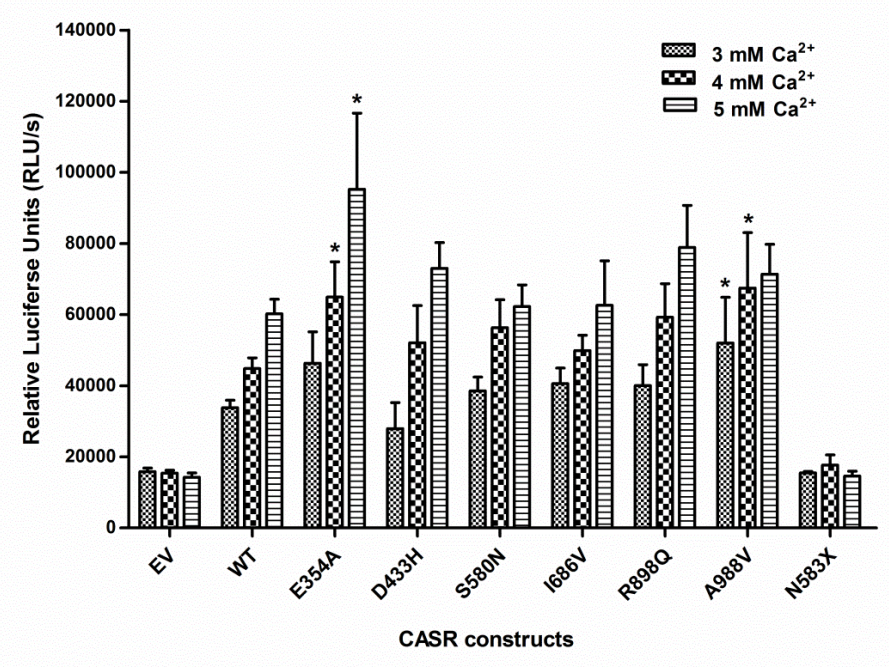

Figure 2.7: Effect of *CASR* mutations on MAPK signaling in response to extracellular calcium: The signaling activity of HEK293T cells transfected with control, WT or mutation-harbouring (E354A, D433H, S580N, I686V, R898Q, A988V) CASR constructs at 3 mM, 4 mM and 5 mM extracellular Ca^{2+} concentrations. The values are plotted as mean ± SEM obtained in three independent experiments. The P values < 0.05 (two-tailed) were regarded significant (unpaired Student's t test, GraphPad Prism 5).

As the wild-type CASR receptor exhibited an exponential increase in signaling activity at 3mM, 4mM and 5mM extracellular Ca^{2+} (Figure 2.6a), the signaling response of mutant CASR receptors was compared to that of wild-type CASR at these three Ca^{2+} concentrations by a bar graph representation (Figure 2.10). The mutation p.Ala988Val, showed significantly higher signaling response than the wild-type CASR at extracellular Ca^{2+} concentrations of 3 mM and 4 mM ($p < 0.05$) (Figure 2.7). The p.Glu354Ala mutant receptor also exhibited an enhanced response than wild-type CASR at 4 mM and 5 mM Ca^{2+} concentrations ($p < 0.05$). The maximum response by p.Glu354Ala and p.Arg898Gln receptors, observed at 6 mM Ca^{2+} was significantly higher than that of the wild-type CASR receptor ($p \leq 0.01$). The reduced EC50 values and enhanced signaling response (at 3 mM, 4 mM, 5 mM and 6 mM Ca^{2+} concentrations) generate a leftward shift in the dose-response curves of p.Glu354Ala, p.Ile686Val, p.Arg898Gln and p.Ala988Val mutant receptors, suggesting a significant gain-of-function effect. The p.Asp433His and p.Ser580Asn mutations caused only slight differences in the dose-response and EC50 values, as compared to wild-type CASR suggesting subtle-effects of these variants on CASR-regulated MAPK pathway. Taken together, it does seem that the CASR mutant receptors exhibit variable gain-of-function effect for the MAPK signaling.

2.3.6 Effect of CASR mutations on intracellular IP1 levels

The effect of CASR wild-type and mutant receptors on Phospholipase C (PLC) coupled Inositol 1,4,5-trisphosphate (IP3) pathway in response to extracellular Ca^{2+} was examined by measuring intracellular IP1 accumulation by IP-One ELISA reagents. As the lifetime of IP3 is less than 30 seconds in the cell, the levels of IP1 were quantified by competitive ELISA in presence of LiCl (prevents conversion of IP1 to Myo-inositol) (Figure 2.8). The cells treated with stimulation buffer without $CaCl_2$ were considered unstimulated for each experiment.

The transiently expressed wild-type CASR, in cultured HEK293T cells exhibited a sigmoidal dose-response curve for increasing extracellular calcium concentrations (0, 2, 4, 6, 8, 10 mM) with an EC50 (agonist concentration at half of the maximal

response) of 4.05 ± 0.13 mM (mean ± SEM). As compared to the wild type CASR, EC50 values of the receptors carrying mutations were as follows: p.Glu354Ala: 3.25 ± 0.18 mM ($p<0.01$), p.Ser580Asn: 3.38 ± 0.16 mM ($p<0.01$), p.Arg898Gln: 3.05 ± 0.18 mM ($p<0.001$), p.Ala988Val: 3.42 ± 0.23 mM ($p<0.05$) suggesting a gain-of-function effect (Figure 2.9). However, the change in EC50 values for the p.Asp433His (3.78 ± 0.16 mM) and p.Ile686Val (3.79 ± 0.2 mM) alleles were not significant. The signaling response curves for p.Glu354Ala, p.Ser580Asn, p.Arg898Gln and p.Ala988Val showed a leftward shift and saturation at a lower Ca^{2+} concentration as compared to wild-type CASR. The cells transfected with control vectors (pcDNA3.1 and CASR-Asn583X pcDNA3.1) had no change in intracellular IP1 levels due to increasing calcium concentration.

Due to an exponential increase in the intracellular IP1 levels in wild-type CASR transfected cells at 3 mM, 4 mM and 5 mM extracellular Ca^{2+}concentrations (Figure 2.9a), IP1 accumulation in cells transfected with the mutant CASR receptors was compared to that of wild-type CASR at these three Ca^{2+} concentrations in a bar graph representation (Figure 2.10).

Ca^{2+} concentration (mM)

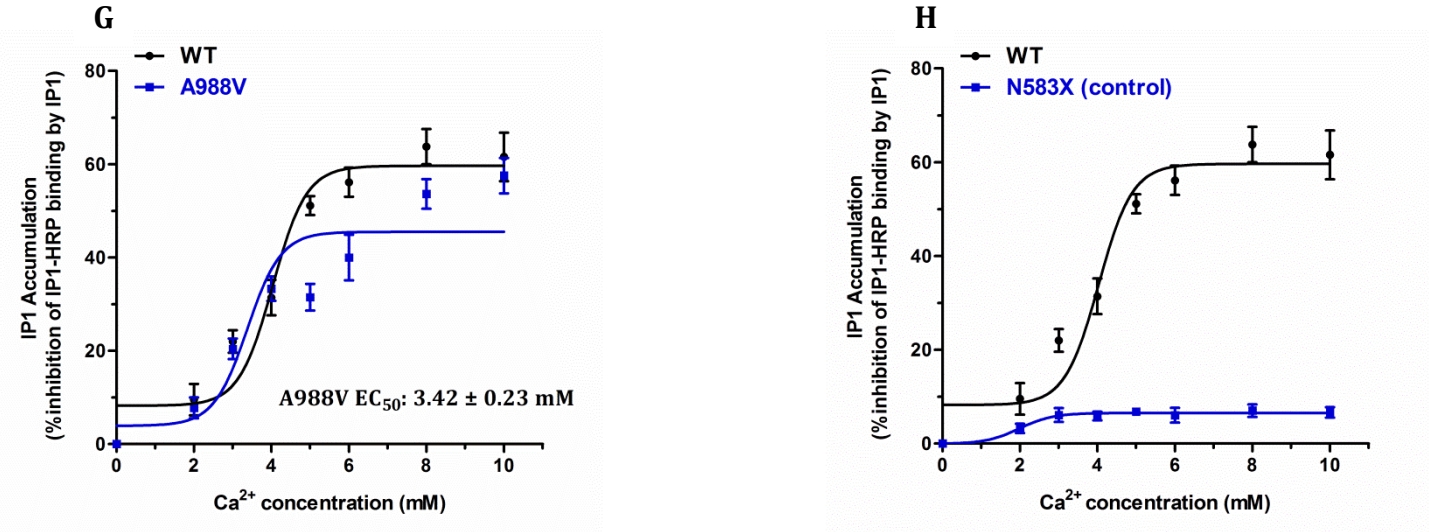

Figure 2.9: Cell signaling (PLC-IP3 pathway) of wild-type and mutant CASR receptors in transfected HEK293T cells: The PLC-mediated IP3 signaling activity is observed by measuring intracellular IP1 accumulation. Changes in IP1 accumulation in response to increasing extracellular Ca^{2+} concentrations were measured in HEK293T cells transiently transfected with control (pcDNA3.1 vector or CASR-N583X), wild-type (WT) or mutation harbouring (E354A, D433H, S580N, I686V, R898Q, A988V) *CASR* cDNA constructs. In each concentration-response curve, activity response of WT is presented in black, whereas, of mutant receptor is shown in blue. The basal level effect in cells with control vectors is shown in plots A and H. The dose-response curves showing changes in intracellular IP1 levels for mutant receptors are presented in graphs B-G. IP1 accumulation was measured using IP-One ELISA Kit and is shown here as the percentage inhibition of IP1-HRP binding (mean ± SEM), obtained from readings of six independent experiments.

The p.Arg898Gln exhibited significantly high levels at 3 mM and 4 mM Ca^{2+} concentrations than the wild-type CASR ($p<0.05$) (Figure 2.10). The HEK293T cells transfected with p.Ala988Val mutant receptor showed significantly reduced intracellular IP1 levels than wild-type CASR at 5 mM ($p<0.001$) and 6 mM ($p<0.05$), exhibiting saturation at lower calcium levels. The significantly leftward shifted dose-response curves of p.Glu354Ala, p.Ser580Asn, p.Arg898Gln and p.Ala988Val mutant receptors indicate an enhanced responsiveness towards calcium and a gain-of-function effect. However, p.Asp433His and p.Ile686Val mutant CASR receptors appear to have a subtle functional effect on the signaling pathway. Yet again, the CASR mutations seem to be of activating nature causing a variable gain-of-function effect on the CASR-regulated IP3-IP1 signaling pathway.

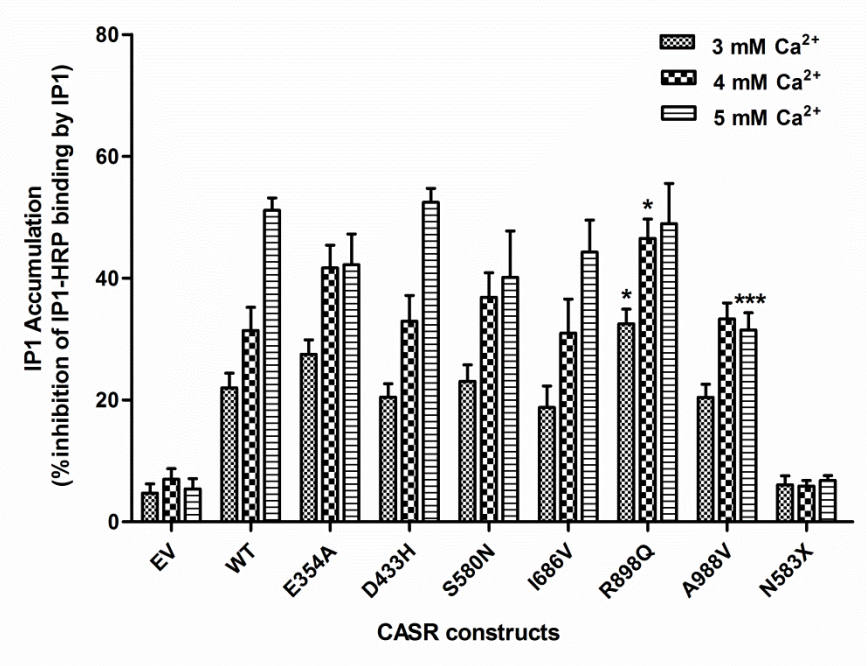

Figure 2.10: Effect of *CASR* mutations on PLC-IP3 signaling in response to extracellular calcium: The intracellular IP1 levels in HEK293T cells transfected with control, WT or mutation-harbouring (E354A, D433H, S580N, I686V, R898Q, A988V) CASR constructs at 3 mM, 4 mM and 5 mM extracellular Ca^{2+} concentrations. The values represented here are of the percentage inhibition of IP1-HRP binding (mean ± SEM), obtained from readings of six independent experiments. The P values < 0.05 (two-tailed) were regarded significant (unpaired Student's t test, GraphPad Prism 5).

2.4 Discussion

Genetic generalized epilepsies are a common form of human epilepsies with substantial genetic basis to their etiology, and exhibit a complex mode of inheritance (Helbig et al 2008, Greenberg and Stewart 2012, Petrovski and Kwan 2013). Although both generalized and focal epilepsies are well defined clinical entities, co-existence of generalized and focal seizures in certain affected individuals in an age-dependent manner as well as presence of both phenotypes in families with multiple affected members, have been reported (Dimova and Daskalov 2002, Caraballo et al 2004, Nicolson et al 2004, Deng et al 2007, Cerminara et al 2012). These findings have suggested an overlapping genetic predisposition for both generalized and focal epilepsies. A few studies have reported presence of febrile convulsions along with GGE in large kindreds (Wallace et al 2001, Kananura et al 2002, Marini et al 2003, Bonanni et al 2004).

Likewise, a three-generation family (NIH2) from south India was reported with its affected members manifesting generalized and focal seizures along with febrile seizures (Kapoor et al 2008). Whole-genome wide linkage analysis identified a critical genetic interval at 3q13.3-q21 (EIG8) with highest LOD score of 3.05. Sanger sequencing of a few candidate genes had led to finding of a rare disease-segregating variation in calcium-sensing receptor gene (*CASR)*, suggesting it as a plausible cause of GGE in NIH2.

In this study, I reanalyzed this disease-linked genomic interval on chromosome 3 by whole-exome sequencing and examining an extended haplotype of 64 Mb (3p14.2–q21) that was being shared by all affected members of NIH2. This analysis identified five rare alleles in the *EPHA6*, *AB3IBP*, *KIAA1407*, *IQCB1* and *CASR* genes, segregating with the clinical phenotype in NIH2. Of these, only c.2693G>A (p.Arg898Gln) in *CASR* fulfilled the criteria of being a causative mutation i.e. absence in databases (dbSNP and 1000 Genomes) and our control cohort, predictive damaging effect on protein due to the substitution and

evolutionary conservation of the parent amino acid residue. These findings strongly suggest a role of CASR in causation of GGE in NIH2 family.

Human *CASR* gene encodes for extracellular calcium-sensing receptor that localizes to plasma membrane of the cell. It is a seven transmembrane protein that belongs to family C of G-protein coupled receptors (GPCR), with other family members being the metabotropic glutamate receptors (mGluR 1-8), γ-aminobutyric acid B receptors (*GABAB*), Retinoic acid-inducible orphan G protein-coupled (RAIG) receptors and taste receptors (T1R). *CASR* plays an essential role in maintenance of systemic calcium homeostasis and regulates several cellular functions via modulation of different intracellular signaling pathways (Brown and MacLeod 2001, Hofer and Brown 2003, Brown 2013). The physiological observations of certain cells being responsive to small changes in extracellular calcium concentrations suggested the presence of an extracellular calcium sensor at the cell surface. The expression cloning in *Xenopus laevis* oocytes using bovine parathyroid poly (A)+ RNA enabled isolation of BoPCaR (bovine parathyroid Ca^{2+}-sensing receptor) (Brown et al 1993). Since then, extracellular calcium-sensing receptor has been identified in several species and in a wide range of tissues such as bone, kidney, intestine and brain (Garrett et al 1995, Brown and Hebert 1997, Zanotti and Charles 1997, Yamaguchi et al 2002, Cheng et al 2002, Chen and Goodman 2004, Loretz 2008, Bystrova et al 2010). *CASR* from brain was first isolated from cDNA library of rat striatal brain (Ruat et al 1995).

The human CASR receptor is a 1078 amino acid polypeptide, comprising of a large extracellular domain (ECD) of about 600 amino acids, seven transmembrane-spanning domains (TMD) and a large ~200-residue carboxyl-terminal intracellular domain (ICD) (Figure 2.12) (Chattopadhyay and Brown 2000). Its large extracellular domain is structurally similar to that of bacterial periplasmic binding proteins (Venus-fly trap domain) and shares sequence identity with the ECD of mGluRs (Bai 2004). The extracellular domain of CASR has been proposed to contain major Ca^{2+}-binding sites and thus, supporting its role in maintaining systemic calcium homeostasis (Huang et al 2007). CASR forms functional homodimers, the active form of receptor on the cell surface (Bai et al 1998a) and

this dimerization is mediated through conserved cysteine residues of ECD (Hu et al 2000). The seven transmembrane domains are involved in the signal transduction mechanism from the ECD, with its intracellular loops providing interaction domains to its respective G proteins. CASR receptor has conserved domain architecture across species in vertebrates (Figure 2.11). Like many other members of family C of GPCRs, CASR has a distinctly large intracellular domain of 216 amino acids, which plays key role in its cell surface expression, and signal transduction via interaction with various intracellular components (Ray et al 1997, Gama and Breitwieser 1998, Awata et al 2001).

CASR senses extracellular calcium (Ca^{2+}_o) and regulates several cellular processes by modulating different intracellular signaling pathways (Brown et al 2001, Ward 2004, Brown 2013) (Figure 2.13). It regulates the secretion of parathyroid hormone and calcitonin in response to Ca^{2+}_o concentration, wherein it acts via activation of phopholipases C, A2 and D (Kifor et al 1997).

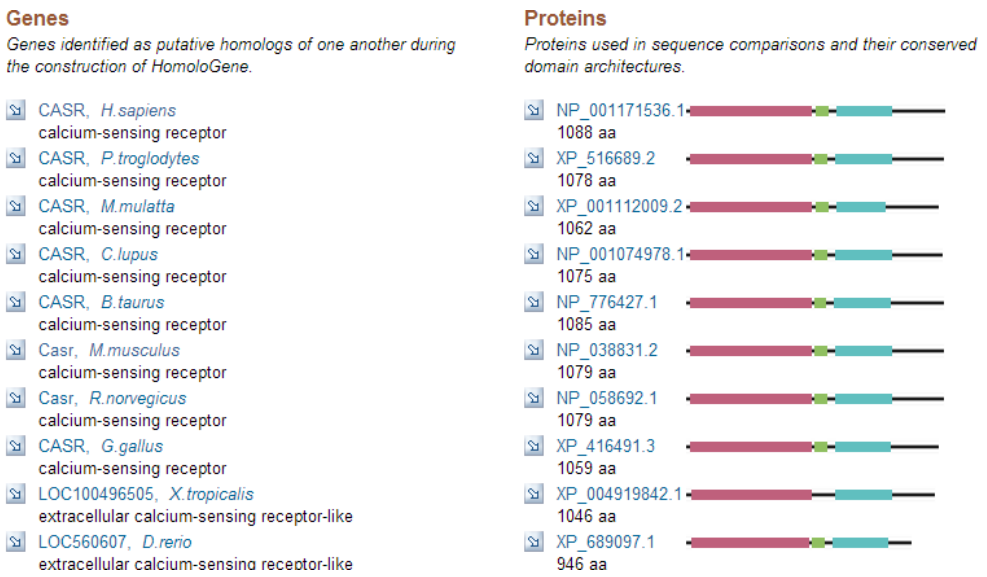

Figure 2.11: Conservation of CASR in Euteleostomi (Homologene, NCBI)

It has also been proposed that *CASR* regulates the fundamental biological processes of cellular proliferation, differentiation and apoptosis in various cell types. *CASR* modulates these functions via interacting with different G proteins, activating PLC mediated IP3 pathway, inhibition of c-AMP, stimulation of the MAPK cascade etc (Darè et al 1998, Kifor et al 2001, Brown et al 2001, Conigrave and Ward 2013). This indicates its role in physiological mechanisms that are apparently quite independent of its role in maintenance of systemic calcium homeostasis.

So far, several studies have shown presence of *CASR* in different brain regions and cell types (Rogers et al 1997, Ferry et al 2000, Kapoor et al 2008, Mudò et al 2009, Chen et al 2010, Ruat and Traiffort 2013), providing a glimpse of its diverse brain-related functions. Expression of *CASR* at transcript and protein level has been observed in different brain regions (Kapoor et al 2008). During development in mice, *CASR* modulates neurite extension in sympathetic neurons and growth of postnatal hippocampal pyramidal dendrites (Vizard et al 2008) and mediates it via ERK1/2 signaling (Vizard et al 2015). A few reports have shown that *CASR* regulates a Ca^{2+}-activated K^{+} channel and a non-selective cation channel (NSCC) in different neuronal cell types and cell lines, thus modulating synaptic plasticity and neurotransmission in neurons (Ye et al 1996, Xiong et al 1997, Chattopadhyay et al 1999a, Chattopadhyay et al 1999b, Chattopadhyay et al 1999c, Phillips et al 2008).

The physiological importance of *CASR* has been established by identifying mutations in this gene in inherited disorders of calcium homeostasis in humans (Egbuna and Brown 2008). Its loss of function mutations are associated with two disorders, familial hypocalciuric hypercalcemia (FHH; MIM: 145980), with one defective copy of gene, and a more severe form of FHH, neonatal severe hyperparathyroidism (NSHPT; MIM: 239200), due to defects in two copies of the gene. The activating mutations that reduce the set point for Ca^{2+} (an enhanced sensitivity to extracellular calcium) are responsible for autosomal dominant hypocalcemia (ADH; MIM: 601198). A few case reports have indicated patients with hypocalcemia manifesting seizures, calcification of basal ganglia or any brain

regions and mental retardation (Pearce et al 1996, Pidasheva et al 2005, Sfar et al 2011, Wong et al 2011), suggesting that derangement in calcium-sensing or homeostasis can have profound effects in normal brain functioning as well.

In this chapter, I present results of whole-exome sequencing analysis of the 64 Mb interval on chromosome 3, confirming the c.2693G>A (p.Arg898Gln) variation in *CASR* to be the epilepsy-causing genetic factor in NIH2. The arginine at 898 amino acid position lies in the intracellular domain of the receptor and is evolutionary highly conserved (Figure 2.12, Figure 2.2c). It is located close to three potential phosphorylation sites for protein kinase C (Thr888, Ser895, Ser915), known to modulate the coupling of *CASR* to intracellular signaling pathways (Bai et al 1998b, Jiang et al 2002). CASR interacts with calmodulin via a calmodulin-binding domain (residues 871-898) in its C-terminus region, and this calcium-dependent association is crucial for its calcium responsiveness and cell surface expression (Huang et al 2010). The ubiquitination and degradation of CASR receptor is mediated by the E3 Ubiquitin Ligase Dorfin, by its region of interaction with dorfin localized to 880-900 residues in intracellular tail (Huang et al 2006). Another report also suggests the gain-of-function effect of p.Arg898Gln and indicates that it disrupts the distal R-K-R motif of the arginine-rich region in ICD leading to abundance of mutant receptor on the plasma membrane (Stepanchick et al 2010). The presence of arginine 898 in the crucial functional domains of the receptor; the calmodulin-binding domain and the dorfin-interacting region, suggests that the alteration of this residue may affect its interactions with other proteins and their mediated functions.

Further, I attempted to gather additional evidence for the role of *CASR* behind causation of epilepsy and was able to identify additional missense mutations in 14 unrelated JME patients (Table 2.6). Among the rare alleles found, effect of six heterozygous missense mutations were evaluated in cell-based functional assays. These mutations occurred at evolutionary conserved residues (p.Glu354Ala, p.Asp433His, p.Ser580Asn, p.Ile686Val, p.Arg898Gln and p.Ala988Val) in CASR (Figure 2.4b). The amino acid residues Glu354, Asp433 and Ser580 are present in the extracellular domain (ECD) of the protein (Figure 2.12).

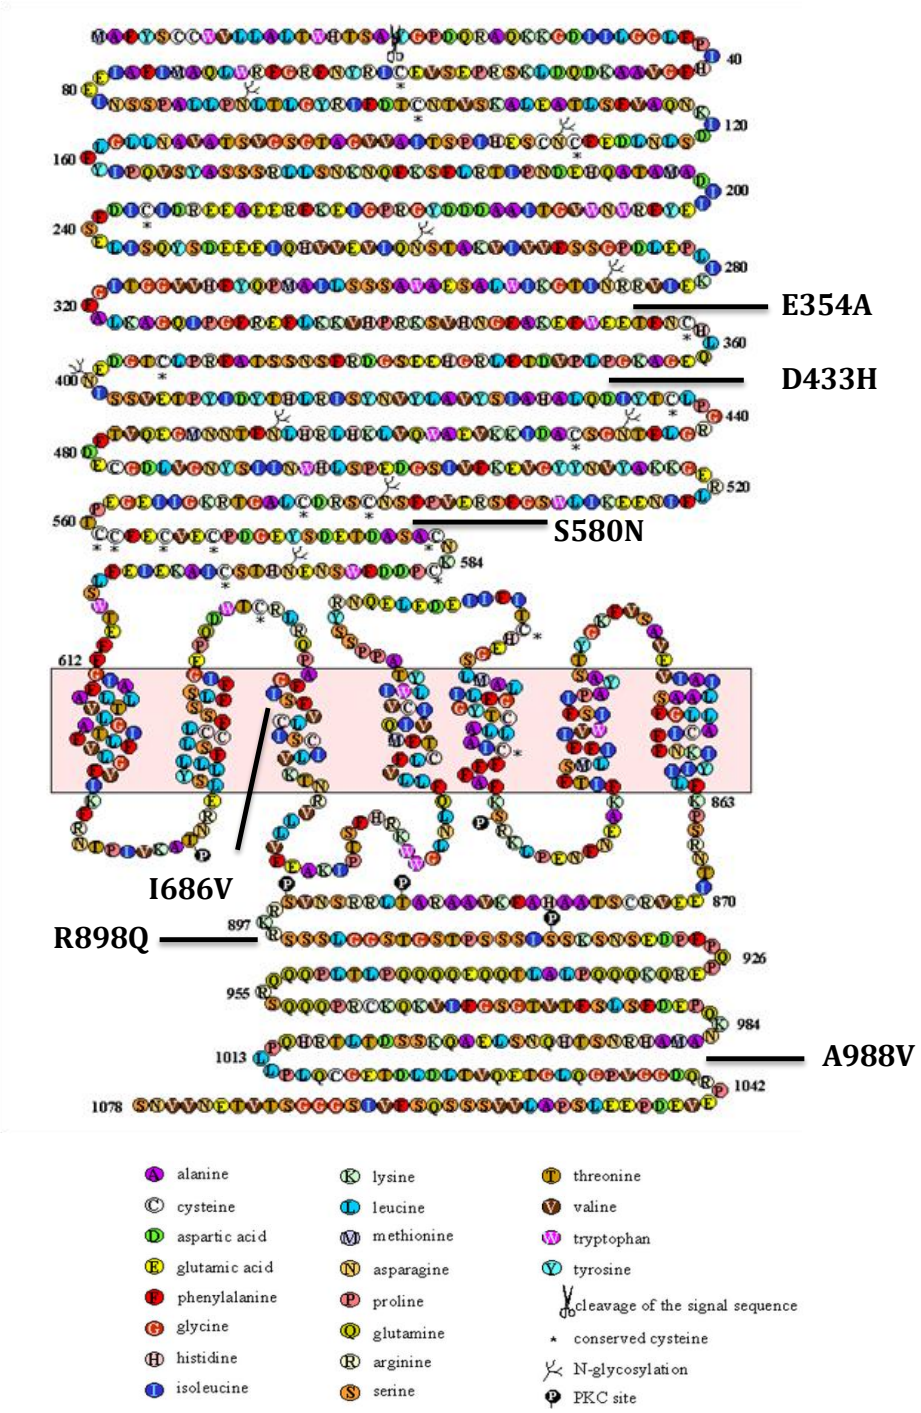

Figure 2.12: Protein sequence and structural topology of CASR: The location of mutations (E354A, D433H, S580N, I686V, R898Q and A988V) identified in JME patients are indicated with a line. CASR comprises of an extracellular domain (1-612 a.a), a seven transmembrane domains (613-862 a.a) and an intracellular domain (863-1078 a.a). The mutations Glu354Ala, Asp433His, Ser580Asn are located in the extracellular domain; Ile686Val is present in the third transmembrane helix; and Arg898Gln and Ala988Val are situated in the intracellular domain of the receptor. (Adapted from www.casrdb.mcgill.ca)

The unusually large extracellular domain of CASR harbors three calcium-binding subdomains, each with two or three predicted Ca^{2+}-binding sites (Huang et al 2009). The Glu354 lies among the crucial amino acid residues in a Ca^{2+}-binding site of the third globular subdomain, suggesting its alteration may affect the conformation or ligand interaction of the calcium-binding site. The Ile686 residue is present in the third transmembrane helix and its substitution to valine may lead to conformational changes affecting the downstream intracellular signaling. The intracellular carboxy-terminal domain (ICD) of CASR has more than 200 amino acid residues and is crucial for its cell surface expression; the ligand-binding modulated downstream signaling and its interaction to proteins such as filamin and calmodulin. Besides p.Arg898Gln, the p.Ala988Val mutation is also located in the intracellular domain of the receptor (Figure 2.12). The Ala988 is present in the filamin-binding domain of ICD, a region essential for CASR-mediated MAPK signaling. CASR interacts with filamin, a scaffolding protein, via a 20-amino acid residue region in ICD and this interaction is known to play a crucial role in the *CASR* mediated-MAPK signaling (Hjälm et al 2001, Awata et al 2001).

Acting via multiple signaling pathways, *CASR* has been proposed to modulate several physiological functions in response to extracellular calcium concentration in a cell- and tissue-specific manner (Figure 2.13). The specific CASR-regulated pathways influencing neuronal excitability in the brain are not yet known. However, CASR is known to regulate Ca^{2+}-activated K^+ channel via p38-MAPK pathway in U87 astrocytoma cells (Ye et al 2004) and the IP3-IP1 signaling regulated-intracellular calcium stores modulate several neuronal functions (Berridge 1998). With this in view, we evaluated the functional effect of the six missense *CASR* mutations on two CASR-regulated signaling pathways: MAPK and IP3-IP1 in relative to wild-type CASR receptor, using transiently transfected HEK293T cells. The signaling activity was measured in the cells transfected with wild-type- or mutant- CASR pcDNA3.1 (+), and cells transfected with pcDNA3.1 (+) vector and the *CASR* cDNA carrying p.Asn583X mutation were considered as controls.

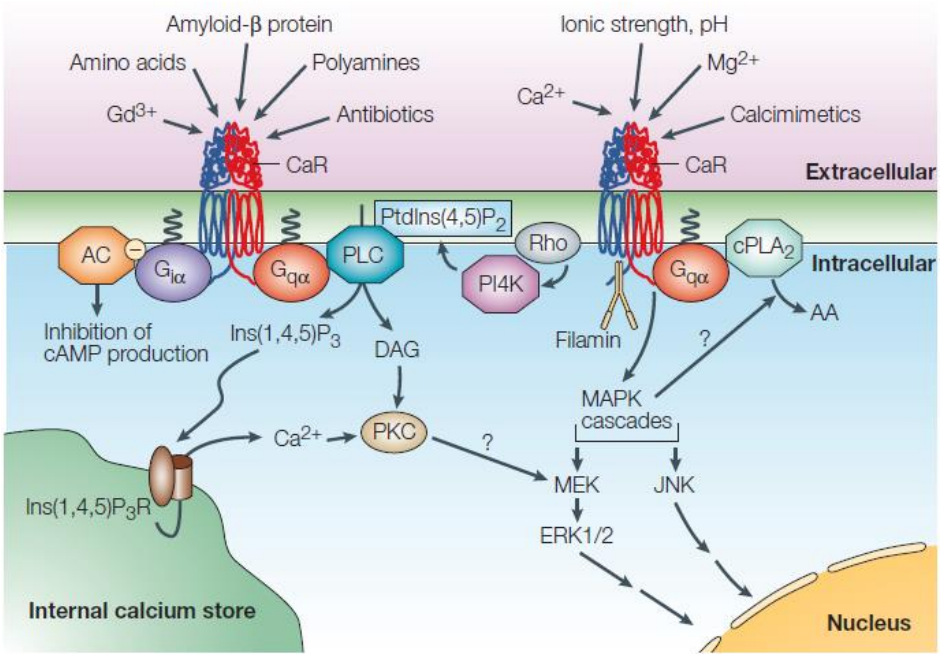

Figure 2.13: CASR-regulated signaling pathways: Several ligands bind to CASR and activate signal transduction cascades, which in turn, regulate various intracellular processes. [AA, arachidonic acid; AC, adenylate cyclase; cAMP, cyclic AMP; cPLA2, cytosolic phospholipase A2; DAG, diacylglycerol; ERK, extracellular-signal-regulated kinase; $G_{i\alpha}$ and $G_{q\alpha}$, α subunits of the i- and q-type heterotrimeric G proteins, respectively; Ins(1,4,5)P3, inositol-1,4,5-trisphosphate; Ins(1,4,5)P3R, inositol-1,4,5-trisphosphate receptor; JNK, Jun amino-terminal kinase; MAPK, mitogen-activated protein kinase; MEK, MAPK kinase; PI4K, phosphatidylinositol 4-kinase; PKC, protein kinase C; PLC, phospholipase C; PtdIns(4,5)P2, phoshatidylinositol-4,5-bisphosphate (from Hofer and Brown 2003)

The wild-type and mutant CASR receptors exhibited a sigmoidal dose-response curve for MAPK and IP3-IP1 signaling on treatment with increasing extracellular Ca^{2+} concentrations. But, the mutant CASR receptors exhibited a variable leftward shift in the dose-response curves of signaling activity. In the MAPK trans-reporting assay, the mutant CASR receptors, p.Glu354Ala, p.Ile686Val, p.Arg898Gln and p.Ala988Val showed significant gain-of-function effect than the wild-type CASR. The leftward shift in the dose-response curves and an enhanced response at crucial Ca^{2+} concentrations (3 mM, 4 mM, 5 mM and 6 mM) suggests these mutations are of activating nature (Figure 2.6 and 2.7). We further assessed the effect of mutations on the signaling activity leading to PLC-mediated 1, 2-diacylglycerol (DAG) formation, thus leading to the IP3/IP1 production, using an

ELISA-based IP-One assay. In IP3-IP1 pathway, the mutant CASR receptors, p.Glu354Ala, p.Ser580Asn, p.Arg898Gln and p.Ala988Val exhibited a significant increased responsiveness towards calcium and saturated at Ca^{2+} concentration lower than that of wild-type CASR (Figure 2.9 and 2.10). Taken together, the CASR mutations, p.Glu354Ala, p.Ser580Asn, p.Ile686Val, p.Arg898Gln and p.Ala988Val apparently have a significant gain-of-function of the CASR-regulated signaling pathways by exhibiting an enhanced responsiveness towards calcium, thus suggesting these to be activating mutations. However, the mild effect of p.Asp433His mutation in altering the signaling activity of CASR receptor suggests, either it is of subtle functional effect and is not solely sufficient to cause functional impairment of the receptor, or it may perturb any other domain-specific CASR function not analyzed here. These findings show that five of six identified epilepsy-associated missense mutations in *CASR* are activating in nature and show a significant gain-of-function effect on the CASR-mediated intracellular signaling.

Similarly, *SLC2A1* mutations in GGE patients are observed to have a spectrum of effects causing marked to mild reduction in the glucose transport by GLUT1 (Arsov et al 2012). Though, no correlation between the severity of seizures in GGE families and functional impairment due to *SLC2A1* mutations was established, the mutations resulting in mild effects on the glucose transport were preferentially observed in families showing variable inheritance pattern. The GGE family with three affected members with JME harbored a mild-effect *SLC2A1* mutation. Such previous reports and our findings indicate that mutations causing relatively moderate effect on the functioning of protein seem sufficient to be causative genetic determinants of GGE/JME.

Our findings indicate a role of CASR in causation of GGE/JME based on the evidence provided at two levels as suggested by McArthur et al 2014. At gene level, all the rare variants in the disease-linked region on chromosome 3, except p.Arg898Gln in CASR, had been excluded based on segregation status in NIH2, allele frequency in databases (dbSNP and 1000 Genomes) and control cohort, evolutionary conservation and predictive pathogenicity using bioinformatics tools. Additionally, we find excess of rare variants in *CASR* in cases than controls and

presence of six rare missense variants in 14 JME patients. The evidence at variant level is provided by their enrichment in cases than controls, strong evolutionary conservation of the variant site, presence in the crucial functional domains of the protein, predictive damaging functional effect and the observed gain-of-function effect of 5 out of 6 variants in the CASR-regulated signaling pathways in HEK293T cells. Additionally, in a large scale study wherein whole exome sequencing was carried out on a group of 118 GGE patients (JME, n=93), a heterozygous rare variation, c.854G>A (p. p.Arg285Gln) in *CASR* was identified in one JME patient (Heinzen et al 2012).

Taken together, we propose that *CASR* is a causative gene for epilepsy with its role predominantly in the GGE/JME phenotype, but also behind seizure types typically not associated with JME, and its potential brain-related functions may underlie its role in susceptibility to epilepsy. Several reports associate activating *CASR* mutations in ADH with hypocalcaemia, muscle cramps, recurrent seizures, basal ganglia calcifications, etc. Seizures are the most frequent symptom associated with ADH, observed in about 56% of the reported pediatric ADH cases (review by Thim et al 2014). And here, we find activating *CASR* mutations linked to a seizure disorder. Thus, it is suggested that gain-of-function effects of *CASR* mutations may perturb the regulation of CASR-activated ion channels or cause an imbalance in calcium homeostasis in the neurons, leading to disruption of synaptic transmission. As the molecular mechanisms how CASR signaling regulates ion channels or other brain-related functions is not yet established, the direct effect of these activating mutations in causing seizure onset is not clear. Thus, it is essential to explore and understand the role of *CASR*-regulated mechanisms in the brain to completely comprehend its role in pathophysiology of epilepsy.

Chapter 3

Exome sequencing reveals a mutation in *TMEM171* at EJM4

EJM4 (5q12-q14) was identified in a three-generation south Indian family (GLH5) with several of its members affected with JME (Kapoor et al 2007). I have carried out whole-exome sequencing (WES) to discover the causative factor in GLH5. Analysis of all WES variants in the 5q12-q14 region led to identification of two novel variants co-segregating with JME. These were c.476G>C in TMEM171 and c.1873-22A>G in COL4A3BP. These variants were found absent in databases and our control cohort. Bioinformatics analysis suggested c.476G>C (p.Gly159Ala) in TMEM171 to be a damaging variant and c.1873-22A>G in COL4A3BP capable of forming an additional splice-site. The c.476G>C variant in TMEM171 converts a highly conserved residue, glycine to alanine (p.Gly159Ala) and is predicted to have a potentially pathogenic effect. A minigene-based splicing assay carried out for the c.1873-22A>G in COL4A3BP in HEK293T and COS-7 cells, showed absence of any alternate spliced product, indicating that this intronic variant is likely to be an uncommon, benign polymorphism. These results suggest that mutation in TMEM171 is the likely cause of JME in GLH5. Further, to identify additional novel/rare epilepsy-associated variants in TMEM171, I examined the gene sequence in a cohort of 480 JME patients. Besides c.476G>C (p.Gly159Ala), two new variations: c.269A>G (p.Gln90Arg) and c.466C>T (p.Arg156Trp) were found. TMEM171 encodes a proline-rich transmembrane protein with an unknown biological function and localizes to plasma membrane. RT-PCR analysis showed expression of TMEM171 in different human brain regions. Though, the epilepsy-associated mutations in TMEM171 did not seem to affect its membrane localization or expression levels, we propose that they may have a damaging effect on its cellular function/s in the brain.

3.1 Introduction

Genetic linkage studies on families with several of their members affected with juvenile myoclonic epilepsy (JME) have helped identify a number of genes for the disorder. An earlier report from this laboratory identified EJM4 (MIM: 611364), a locus at chromosome 5q12-q14 linked to JME in a three-generation south Indian family, Family GLH5 (Kapoor et al 2007) (Figure 3.1).

In the whole-genome based linkage mapping study involving GLH5, the highest two-point LOD (logarithm of odds) score of 3.33 at recombination fraction (θ) = 0.0, was obtained for D5S641 and D5S459. The proximal limit of the disease-linked haplotype was defined by a recombination event between D5S624 and D5S427 in an affected individual (II:7; Figure 3.1), whereas, a recombination event between D5S459 and D5S428 in another affected individual, III:7, defined the distal boundary of the linked region. On the basis of these two recombination events, the centromeric and telomeric boundaries of the critical EJM4 interval were defined by D5S624 and D5S428, respectively. EJM4 encompasses 25 Mb of the genome and harbors 118 well annotated protein coding genes (GRCh37/hg19).

In this chapter, I present the results of a whole-exome sequencing experiment performed on two affected individuals of GLH5, wherein, a novel heterozygous variation, c.476G>C (p.Gly159Ala) in *TMEM171* was identified as the most probable cause of the disease. *TMEM171* is a relatively poorly characterized gene encoding a proline-rich transmembrane protein with an unknown biological function. To gather additional evidence for the role of *TMEM171* in epilepsy, we examined a group of apparently unrelated JME patients for mutations in this gene. Identification of additional novel and rare epilepsy-associated mutations in *TMEM171* is presented here.

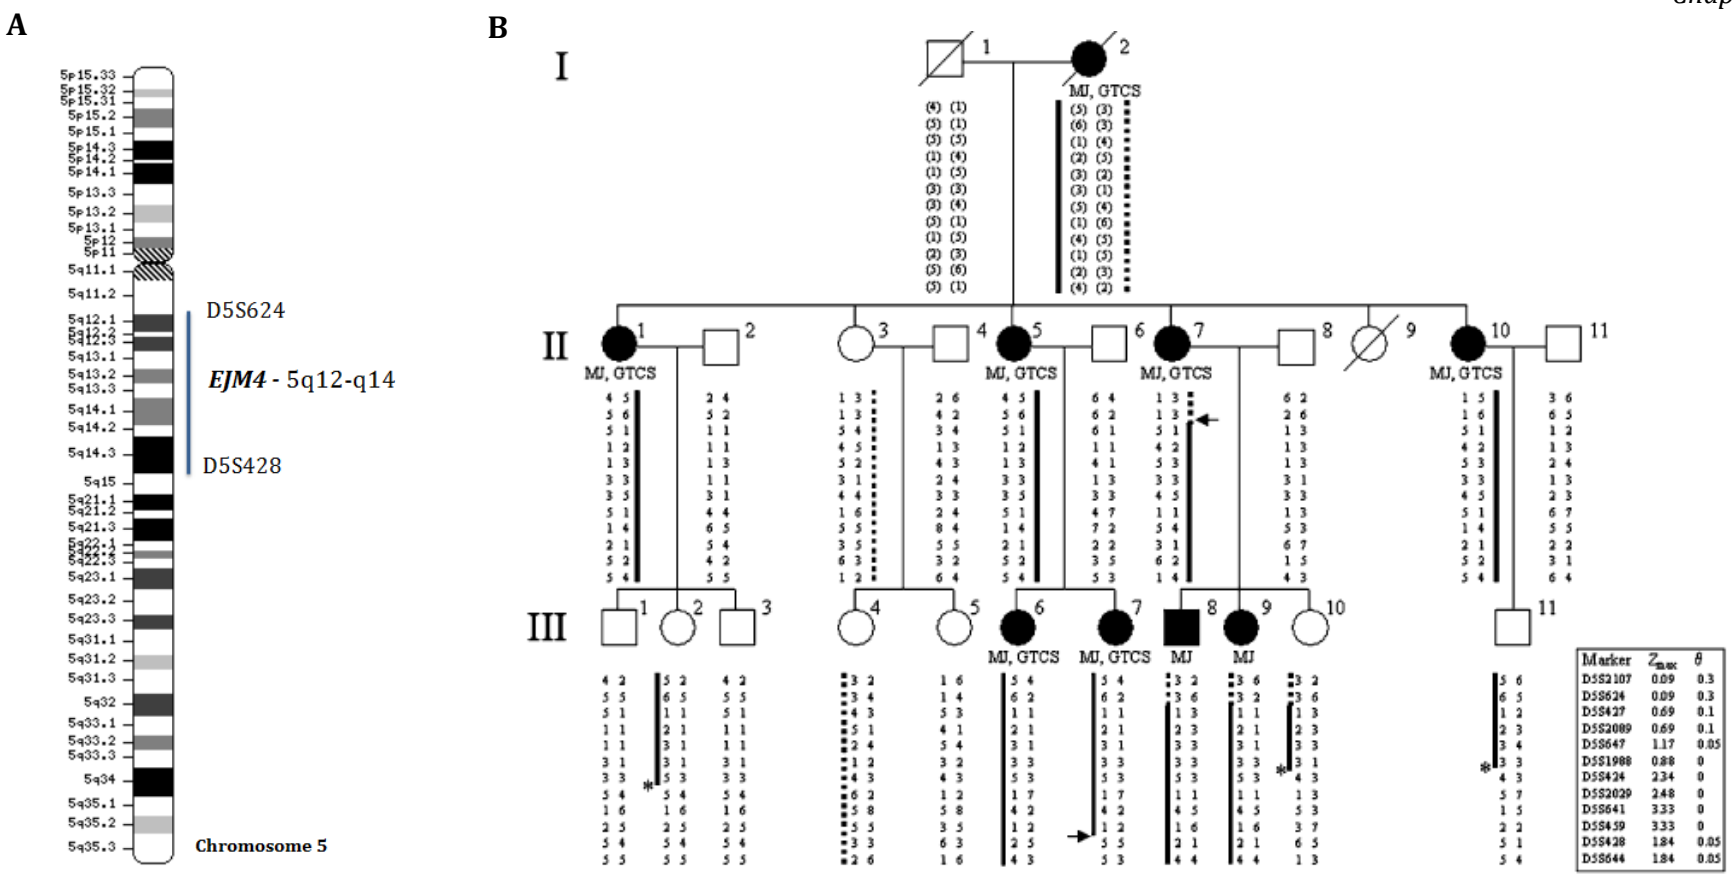

Figure 3.1: The EJM4 locus in Family GLH5: A. Ideogram of chromosome 5 representing the location of the JME locus, EJM4 (5q12-q14). **B.** Pedigree of GLH5 depicting the disease-linked haplotype (EJM4) shared among its affected members and three unaffected members (III:2, III:10 and III:11). Males are denoted by squares and females are denoted by circles. Filled symbols represent affected individuals and empty, unaffected ones. Haplotypes are shown below the symbols. Upper and lower recombination boundaries denoting the critical region are indicated by arrows in individuals II:7 and III:7. Clinical features of affected subjects are indicated along with the symbols (MJ: Myoclonic jerks, GTCS: Generalized tonic-clonic seizures). Adapted from Kapoor et al 2007.

3.2 Materials and methods

3.2.1 Subjects ascertainment and clinical characterization

The three-generation family, GLH5 discussed in this chapter was first reported by Kapoor and colleagues (2007) (Figure 3.1). Of the 24 members in the family, 21 members had consented to participate. They were clinically evaluated by a neurologist according to the guidelines of International League against Epilepsy (ILAE; Commission on Classification and Terminology of the International League Against Epilepsy 1989).

Family GLH5 was ascertained through proband (II:10), who presented distinct characteristics of JME. She had a history of myoclonic jerks (MJ) and generalized tonic-clonic seizures (GTCS) beginning at the age of 14 and 20, respectively. Seizures occurred primarily in the morning after awakening. Her EEG recordings showed generalized spikes, polyspikes and wave discharges (Figure 3.2).

Additional affected members of the family had a history of myoclonic jerks, may be accompanied with GTCS with an age of onset ranging from 12-18 years (detailed description in Table 3.1). At the time of participation in this study, the unaffected subjects reported no history of seizures. For the three deceased members, diagnosis was inferred based on the information provided by other family members. Family GLH5 presents largely homogenous manifestation of JME. For genetic analysis, subjects, I:2, II:1, II:5, II:7, II:10, III:6, III:7, III:8 and III:9 were considered affected and remaining members, unaffected.

A cohort of about 500 apparently unrelated JME patients were ascertained from NIMHANS, SCTIMST and a few epilepsy specialty clinics in south India and were diagnosed according to the guidelines of ILAE. The control cohort comprised of 250 healthy individuals from south India, above 20 years of age and with no apparent family history of neurological disorders. The study was approved by the institutional ethics committees and participating families or individuals provided written informed consent. Ten milliliters of peripheral venous blood was

Table 3.1: Clinical characteristics of the affected individuals of GLH5

Patient ID	Age of onset (years)	Gender	Type of seizures manifested	EEG	Photoparoxysmal response (15Hz)
I:2	_	Female	Myoclonic, GTCS	NA	No
II:1	13	Female	Myoclonic, GTCS	Normal	No
II:5	15	Female	Myoclonic, GTCS	GSW	No
II:7	16	Female	Myoclonic, GTCS	GSW	No
II:10	14	Female	Myoclonic, GTCS	GSW	No
III:6	12	Female	Myoclonic, GTCS	GSW	No
III:7	9	Female	Myoclonic, GTCS	GSW	No
III:8	14	Male	Myoclonic	GSW	Yes
III:9	12	Female	Myoclonic	Normal	No

The affected members of GLH5 exhibited homogenous clinical characteristics of juvenile myoclonic epilepsy. The photoparoxysmal response was observed only in individual III:8. GTCS: generalized tonic-clonic seizures; GSW: generalized spike-wave or polyspike-wave discharges (4-5 Hz); EEG: electroencephalography; NA: not available.

Figure 3.2: Interictal scalp electroencephalogram of proband, II:10 showing generalized polyspike and wave discharges. (Adapted from Kapoor et al 2007)

collected from the participants and genomic DNA was isolated using the phenol-chloroform method (Sambrook and Russell 2001).

3.2.2 Exome sequencing and variant analysis

Genomic DNA from the parent-offspring pair, II:5 and III:6 was used for the next-generation sequencing experiments. Whole-exome sequencing was performed for II:5 and III:6 individuals, using the Agilent SureSelect All Exon 50 Mb Kit. Genomic DNA libraries were constructed from sheared DNA fragments using Agilent's SureSelect XT Target Enrichment System for Illumina Paired-End Sequencing Library. The prepared library was captured using SureSelect™ biotinylated RNA baits and subjected to PCR based amplification (detailed description in chapter 2). The sequencing was then carried out using Genome Analyzer GAIIx (Illumina) obtaining 72 bp paired-end sequence reads.

The raw sequence data (FASTQ) was processed through an in-house analysis pipeline. The quality check was done using SeqQC v2.1 and the low quality bases and 3' adapter sequences were removed. The sequence reads with 70% of its bases having Phred-like quality score ≥ 20 and having a minimum of 50 bp length were considered. The high-quality processed reads were aligned to human genome reference assembly hg19 (GRCh37) using Burrows–Wheeler Aligner (v0.6.0) and PCR duplicates were removed. Coverage statistics for aligned data were calculated using custom scripts (written in Perl) and hg19 reference gtf file format (whole-exome and the 5q12-q14 region interval). Variations and indels were called using Samtools (v0.1.7a) and annotated into functional categories of nonsynonymous variants, synonymous variants, and intronic variants with snpEff (v2.0.5). These changes were further segregated as the known and novel ones, based on their presence/absence in the Database of Single Nucleotide Polymorphisms (dbSNP) 131. The shortlisted variations were then checked in the updated release of dbSNP and 1000 Genomes.

The gene variants located in the epilepsy locus (5q12-q14) were considered for further analysis and the novel/rare heterozygous variations and indels till 3x read

Table 3.2: Summary of the next-generation sequencing data

Statistics	II:5	III:6
Data generated	20.24 Gb	19.48 Gb
Read length in bases (paired end)	72	72
Total number of reads [% of high quality reads[a]]	95194784 [94.12]	91572152 [91.7]
Total number of bases [% of high quality bases[b]]	6.85 Gb [95.01]	6.59 Gb [93.0]
Percentage of non-ATGC characters	0.51	0.52

II:5 and III:6 are the next-generation sequenced individuals of GLH5. [a]Reads with ≥70% bases with Phred score ≥20. [b]Nucleotide bases with Phred-like quality score ≥20. High quality reads are the quality filtered reads from the raw sequence data. [#]Probes used in the Agilent SureSelect Human All Exon 50 Mb kit to capture 51 Mb of exome sequence.

Table 3.3: Sequence coverage summary for the SureSelect probe region in the whole-exome sequencing experiment

Percentage of probe region covered*	Whole-exome		Chr 5 region (5q12-14)	
	II:5	III:6	II:5	III:6
Total probe region	96.29	96.01	98.07	98.07
Read depth ≥ 5x	90.64	89.93	96.45	96.39
Read depth ≥ 10x	85.89	84.78	95.15	94.94
Read depth ≥ 15x	81.63	80.11	93.49	93.45
Read depth ≥20x	77.53	75.52	91.61	91.18

*Percentage of SureSelect probe region coverage calculated after sequences were aligned to Human genome reference sequence (hg19/GRCh37). Chr, chromosome.

depth were examined and verified. Careful examination of all annotated protein coding genes at 5q12-q14 helped identify a few coding exons with no or poor sequence read coverage in the exome data set. These low coverage exonic regions were PCR amplified, sequenced and examined.

3.2.3 Validation of novel/rare variants (NGS-chr 5 region)

Sanger sequencing was carried out to validate the novel and rare variants identified in the exome data set of individuals II:5 and III:6. Primers were designed spanning the variant-harboring amplicons and low coverage exonic regions, using online tools, Primer3 and Oligocalc (Appendix II A3.2). Amplification by polymerase chain reaction (PCR) was performed using 100 ng of genomic DNA in a reaction volume of 20 µl containing 0.25 µM of each forward and reverse primer, 800 µM of dNTPs (200 µM of each dNTP), 1x reaction buffer (50 mM KCl, 20 mM Tris-HCl pH 8.4), 1.5 mM $MgCl_2$ and 1 U of *Taq* polymerase (Invitrogen). The amplifications were carried using a GeneAmp® 9700 at their respective standardized annealing temperatures. The sequencing was performed using the BigDye Terminator Cycle Sequencing reagents (Applied Biosystems) on an ABI3730 Genetic Analyzer (detailed method in chapter 2). The sequences thus obtained were aligned to the respective reference gene sequences obtained from the RefSeq database (NCBI) using SeqMan II v5.01 (DNASTAR Inc.). A family-based segregation analysis was carried out for the rare and novel heterozygous variations that were common to the next-generation sequenced samples (II:5 and III:6). The gene variants which co-segregated with epilepsy in the Family GLH5 were further examined in the control cohort of 250 individuals.

3.2.4 Bioinformatics analysis of novel/rare disease-segregating variants (NGS-chr 5 region)

Various *in silico* tools were employed to predict the potential pathogenic impact of the novel/rare segregating variants and to observe the evolutionary conservation of the amino acid residue altered due to the nonsynonymous variation in the protein. The effect of nonsynonymous change/s was predicted using SIFT, Polyphen-2, Align-GVGD, SNAP (screening for non-acceptable polymorphisms) and PMut. Whereas, to assess the effect of intronic variant/s, tools such as NetGene2

and NNSPLICE 0.9 (BDGP-Berkeley Drosophila Genome Project) were used. Multiple protein sequence alignment of TMEM171 from different organisms was carried out by Clustal Omega. The respective reference TMEM171 protein sequence of each organism was taken from NCBI (Appendix II A3.3).

3.2.5 Minigene construction

The predicted effect of an intronic variant c.1873-22A>G in *COL4A3BP* on splicing of exons 15 and 16 of the gene, was studied by constructing a minigene from this gene region. The variant in question is positioned 22 bases upstream of exon 16 (NM_001130105.1, ENST00000380494). The minigene comprised exons 15, 16 and the intervening intron (Figure 3.5). The ~2.7 kb (2764 bp) insert of minigene was amplified from the genomic DNA of an affected individual of GLH5 family, carrying c.1873-22A>G variation in the heterozygous state. The primers used for amplification were, forward- 5'-tcttcaaagcttcaactatagaaaactttcatgtggtgg-3' and reverse- 5'-acatgtctcgagaggagcactgtcatgatccacag-3'. PCR was done in a 50 µl volume containing 200µM of each dNTP, 2 mM $MgSO_4$, 0.4 µM of each primer, 100 ng of genomic DNA and 1U Platinum® Taq High Fidelity (Invitrogen). Amplification was performed using a GeneAmp® 9700 at following conditions: initial denaturation at 94°C (1 minute), followed by 18-20 cycles of denaturation at 94°C (30 seconds), annealing at 55°C (30 seconds) and extension at 68°C (3 minutes) followed by final extension at 72°C (7 minutes). The amplified products were electrophoresed and visualized on a 0.8% agarose/TAE/EtBr gel (Figure 3.6a). The amplified minigene-insert was purified using QIAquick® PCR purification reagents (Qiagen) and its identity was confirmed by sequencing using insert-specific primers (Appendix II A3.2). The 2764 bp minigene-insert was cloned into pcDNA3.1 (+) (Invitrogen), mammalian expression vector, using HindIII and XhoI restriction enzyme sites. As the genomic DNA template carried the heterozygous variation, screening of the 'positive' colonies helped identify both wild-type (G) and variation (A) harboring vectors (Figure 3.6b). The wild-type and variant carrying minigene pcDNA3.1 (+) vectors were prepared using QIAprep Spin Miniprep Kit (Qiagen) and used to study the splicing of exons 15 and 16 of *COL4A3BP* in the cultured cells.

3.2.6 Cell culture and transient transfections

HEK293T and COS-7 cells were grown in T-25 flasks (BD Biosciences) and were sub-cultured when at 70-80% confluence. The cells were cultured in Dulbecco's modified Eagle's medium (DMEM) (Sigma) supplemented with 10% heat-inactivated FBS (Sigma), 2 mM L-glutamine (Sigma) and antibiotics (100 U/ml penicillin and 10 mg/ml streptomycin, Sigma) in a humidified atmosphere of 5% CO_2 at 37°C. For transient transfections, culture media of the cells was replaced to antibiotic- and serum- free DMEM. The transfections were performed using Lipofectamine™ 2000 (Invitrogen) following the manufacturer's instructions at a ratio of 1:1 for DNA to transfection reagent (for a 35 mm dish, 2 µg of plasmid DNA: 2 µl of Lipofectamine™ 2000). Six hours post-transfection, the media in culture dishes was changed to serum containing DMEM.

For minigene splicing analysis, HEK293T and COS-7 cells were sub-cultured in 35 mm dishes and used for total RNA isolation after 36 hours of transfection. For cellular localization experiment, HEK293T cells were sub-cultured in 35 mm dishes containing poly-L-lysine (0.1 mg/ml, Sigma) coated coverslips and in 6-well plates for western blot analysis. Immunocytochemistry experiments and whole cell protein extraction for western blot analysis were performed 36-48 hours after transfection.

3.2.7 RT-PCR and splicing analysis of minigene transfected cells

Thirty six hours post-transfection, total RNA was isolated from the minigene-transfected HEK293T cells, using the trizol method. One ml of Trizol reagent (Gibco BRL, Life Technologies) was used per 35 mm culture dish. Precipitated RNA was treated with DNAse I (New England Biolabs) for removal of contaminating genomic DNA if any. The cDNA was synthesized using SuperScript™ III First-Strand Synthesis System for RT-PCR (Invitrogen) from 2 µg of isolated RNA using random hexamers following the manufacturer's instructions. The control reaction (RT-) for cDNA synthesis from wild-type (WT) and mutant/variant-harboring (MT) minigene transfected cells was done in absence of SuperScript™ III reverse transcriptase. The spliced product from two exons (exon 15 and 16 of *COL4A3BP*) of wild-type and mutant/variant-harboring

minigene was amplified by PCR using T7F and BGHR primers from the synthesized cDNA (Appendix A3.2). Human β-actin gene primers provided along with the cDNA synthesis system (sense primer: 5'-GCTCGTCGTCGACAACGGCTC-3', antisense primer: 5'-CAAACATGATCTGGGTCATCTTCTC-3') were used as control. The amplified products of minigene constructs, control reactions (RT-) and human β-actin control reactions were visualized by 2% agarose/TAE/EtBr gel electrophoresis.

3.2.8 Mutational analysis of TMEM171

The coding exons and intron-exon boundaries of *TMEM171* (NM_173490.7, ENST00000454765) were Sanger sequenced in 480 JME patients and 240 control individuals. Primer pairs for PCR amplification of the exons were designed using online tools, Primer3 and OligoCalc (Appendix II A3.2). PCR amplification of individual fragments was performed at their respective standardized conditions on a GeneAmp® 9700 as described earlier. The amplified products were purified and cycle sequencing was performed. DNA sequencing was carried out using BigDye Terminator Cycle Sequencing kit v3.0 and ABI 3730 Genetic analyzer (detailed protocol in chapter 2). The sequences were compared to *TMEM171* reference gene sequence (NM_173490.7) (RefSeq, NCBI) using SeqMan II v5.01 and the sequence variants were identified.

3.2.9 Bioinformatics analysis

To predict the possible effect of novel/rare nonsynonymous mutations in *TMEM171* identified in JME patients, *in silico* tools, SIFT, Polyphen-2, and Align-GVGD was used. The TMEM171 protein sequence (NP_775761.4) from NCBI was used as the input file for these tools. The evolutionary conservation status of the amino acid residues altered due to the nonsynonymous mutations was evaluated by performing multiple protein sequence alignment of TMEM171 from various organisms using Clustal Omega. The TMEM171 protein sequence of each organism was obtained from NCBI (Appendix II A3.3).

As *TMEM171* encodes for an uncharacterized protein, we used online databases such as NCBI and GeneCards to acquire any available information. The TMEM171

protein was studied using bioinformatics tools, TMHMM and PRED-TMR to evaluate its predictive transmembrane regions. To predict the sub-cellular localization of the TMEM171 protein, LOCTREE 3 tool was employed.

3.2.10 Expression analysis of TMEM171 in the human brain

The presence of the *TMEM171* transcript in different regions of human brain was evaluated by RT-PCR (Reverse transcriptase-PCR) using Marathon-Ready™ cDNAs from hippocampus, cerebral cortex, hypothalamus and cerebellum (Clontech). The source of poly A^+ RNA for these cDNAs is pooled from brains tissues of Caucasian male/female aborted fetuses or adults that died of sudden death. A set of intron-spanning primers 5'-GCCCAGTGCCTTATCTTTGG-3' and 5'TAGTTCCAGGACTCTCAGCG-3' located within exon 1 and exon 2 of *TMEM171*, respectively were used for the amplifications. PCR was performed in a 20 µl reaction volume containing 0.5 ng of Marathon-Ready™ cDNA, 0.25 µM of each primer, 800 µM of dNTPs (200 µM of each dNTP), 1.5 mM $MgCl_2$, 1X reaction buffer (50 mM KCl, 20 mM Tris-HCl pH 8.4) and 1 U of *Taq* DNA polymerase (Invitrogen). PCR amplification was performed on GeneAmp® 9700 at the following conditions: initial denaturation (94°C, 5 minutes), followed by 35 cycles of denaturation (94°C, 30 seconds), annealing (58°C, 30 seconds) and extension (72°C, 30 seconds), and followed by final extension at 72°C for 10 minutes. The amplified products were verified by 1.5% agarose/TAE/EtBr gel electrophoresis. The products were then purified and subjected to bi-directional DNA sequencing on an ABI3730 Genetic analyzer. The amplification of cDNA fragment using the same primer pair from a plasmid containing the *TMEM171* cDNA cloned in pcDNA3.1(+) vector was regarded as a positive control, and no DNA template reaction was considered, negative control.

3.2.11 Generation of TMEM171 cDNA wild-type and mutant constructs

The wild-type cDNA of *TMEM171* transcript (NM_173490.7, CCDS4017.1) cloned in pCMV6-AC-GFP expression vector was obtained from OriGene (Cat. No. RG205538). The identity of the clone was verified by sequencing using overlapping insert-specific primers (Appendix II A3.2). For sub-cloning into the

mammalian expression vector pcDNA3.1 (+), *TMEM171* cDNA of 975 base pairs (bp) encoding a protein of 324 amino acids was amplified from pCMV6-AC-GFP-TMEM171 vector. PCR amplification was performed using a primer pair 5'-GCTGGCTAGCGCCACCATGTCTCCTGCAGCTGCTGCT-3' (forward) and 5'-TAGACTCGAGTTACGGTGGGGAAGGCTCAGA-3' (reverse), harboring sites for restriction enzymes NheI and XhoI, respectively. Amplification was done in a reaction volume of 50 µl using 100 ng of pCMV6-AC-GFP-TMEM171 plasmid, 0.25 µM of each primer, 800 µM of dNTPs (200 µM of each dNTP), 1 mM $MgSO_4$, 1x Pfx amplification reaction buffer (Invitrogen) and 1 U of Platinum Pfx *Taq* DNA polymerase (Invitrogen). The conditions followed for amplification were: initial denaturation (94°C, 5 minutes), followed by 25 cycles of denaturation (94°C, 30 seconds), annealing (55°C, 30 seconds) and extension (72°C, 60 seconds), and followed by final extension at 72°C for 10 minutes. The amplified cDNA was visualized by 0.8 agarose/TAE/EtBr gel electrophoresis and purified using QIAquick® PCR purification kit (Qiagen) (Figure 3.10). The cDNA insert was cloned using Quick T4 DNA ligase (New England Biolabs) into the pcDNA3.1 (+) mammalian expression vector (Invitrogen) as a NheI-XhoI (New England Biolabs) fragment. Plasmid DNA was isolated from positive bacterial clones using QIAprep Spin Miniprep Kit (Qiagen). The identity of the cloned insert was verified by its sequencing using vector-specific primers (T7F and BGHR) and overlapping insert-specific primers (Appendix II A3.2) using BigDye Terminator v3.0 Cycle sequencing Ready Mix on an ABI3730 Genetic Analyzer. The *TMEM171* cDNA insert sequence was compared to its reference sequence (NM_173490.7, CCDS4017.1) (RefSeq, NCBI) using SeqMan II v5.01.

The *TMEM171* cDNA constructs harboring mutations were generated by site-directed mutagenesis using QuikChange® II XL mutagenesis reagents (Stratagene). The mutagenic oligonucleotide primer pairs (Appendix II A3.2) were designed to incorporate point mutations in the cDNA and subsequently used for amplification of wild-type *TMEM171* pcDNA3.1 vector by Pfu Turbo DNA polymerase. After digestion of the parental DNA construct with DpnI for 1 hour at 37°C, E.coli XL-10 cells were transformed with 2-5 µl of reaction containing amplified DNA with incorporated nucleotide substitution. The transformants were screened by

sequencing of the mutated cDNA plasmid using the overlapping insert-specific primers as described earlier.

3.2.12 Cellular localization by fluorescence immunocytochemistry

HEK293T cells grown on poly-L-lysine coated coverslips were transiently transfected with wild-type or mutant *TMEM171* pcDNA3.1 (+) constructs. After 36 hours of transfection, cells were rinsed three times with 1X phosphate buffered saline (PBS) and fixed using 2% paraformaldehyde (Sigma) in PBS for 15 minutes at room temperature. PBS-washed cells were treated with blocking solution (3% BSA with or without 0.1% Triton X-100) for one hour at room temperature. The transfected cells were treated at two conditions separately: non-permeabilized (absence of Triton X-100) and permeabilized (in presence of Triton X-100). Cells were then incubated with polyclonal anti-TMEM171 mouse raised antibody (Sigma) (2 µg/µl) in 1X PBS with 1% BSA for one hour at room temperature. After washing the cells three times with 1X PBS-1% BSA solution, they were incubated for an hour with Alexa Fluor® 568 goat anti-mouse IgG (Molecular Probes) at a dilution of 1:500 in 1X PBS-1% BSA at room temperature. The washed cells were stained with DAPI (0.2 µg/ml) for 10 minutes and then given three washes with PBS to remove excess stain. The stained coverslips were mounted on glass slides using mounting medium (Sigma) and dried overnight. Confocal images of labeled cells were acquired using a LSM 510 Meta (Carl Zeiss) and photomicrographs were taken with a 63x/63x zoom oil immersion objective.

3.2.13 Protein expression analysis by immunoblot analysis

Forty-eight hours post-transfection, cell lysates were prepared from HEK293T cells transiently transfected with wild-type and mutant *TMEM171* pcDNA3.1 (+) constructs. The cells were washed thrice with 1X PBS. The cells were then dislodged in PBS and resuspended in RIPA buffer (150 mM NaCl, 10 mM Tris pH 7.5, 0.1% SDS, 1% Triton X-100, 1% Sodium deoxycholate, 5 mM EDTA) supplemented with protease inhibitor cocktail (1:1000, Sigma), on ice for 30 minutes. The cell lysate was intermittently passed through 26 gauge needle attached to a 1 ml syringe for complete lysis. The lysate was centrifuged at 14000 rpm for 20 minutes at 4°C to remove the cell debris and the cell lysate in the

supernatant was used for western analysis. The total protein content in the whole cell lysates was determined using the bicinchoninic acid assay kit (Sigma). About 20 µg of total protein was subjected to SDS-containing polyacrylamide gel electrophoresis (PAGE) (12%). The proteins on the gel were subsequently electrotransferred (Bio-Rad) to nitrocellulose membrane (GE Healthcare) at 20V for one hour. The membrane was blocked [2% BSA (bovine serum albumin, Sigma) in PBS containing 0.05% Tween-20 (Sigma)] for four hours at 4°C. It was then incubated with polyclonal anti-TMEM171 mouse raised antibody (1 µg/µl, Sigma) in PBS containing 1% BSA and 0.05% Tween-20 for 10-12 hours at 4°C. The membrane was then washed four times with wash buffer (0.05% Tween-20 in PBS), each for 15 minutes at room temperature. It was further incubated with horseradish peroxidase (HRP)-conjugated, rabbit anti-mouse IgG (Bangalore Genei) in PBS containing 1% BSA and 0.05% Tween-20 (1:10000 for 3 hours at 4°C). After washing the membrane with wash buffer (4 X 15 minutes), it was treated with enhanced chemiluminescent (ECL) substrate for HRP (Pierce) for 5 minutes and exposed to film to visualize the ECL signal. The α-Tubulin was used as control, wherein after transfer of cell lysate protein onto the nitrocellulose membrane blot, it was treated separately. The control protein membrane was blocked for 4 hours at 4 °C, incubated with monoclonal anti-α-Tubulin mouse raised antibody (Sigma) (1:10000 dilution for 10-12 hrs, 4°C), followed by treatment with 1:10000 dilution of HRP-conjugated rabbit anti-mouse IgG (Bangalore Genei) for 3 hours at 4°C. The steps of washing and detection remained same as above.

3.3 Results

3.3.1 Analysis of the variants from whole-exome sequencing (5q12-q14)

To identify the genetic cause of JME in Family GLH5, genomic DNA of an affected parent-offspring pair (II:5 and III:6) was subjected to whole-exome sequencing using Agilent SureSelect 50 MB Kit. An average of 19 Gb per sample of raw sequence data was generated (Table 3.2). The SeqQC v2.1 reported an average of 93% reads with high quality (≥ 70% bases in a sequence read with Phred-like

[a]Genomic position of the nucleotide base on chromosome 5 (chr 5) (GRCh37, NCBI). [b]Nomenclature of variants in introns or UTR is with respect to first base of the corresponding cDNA. The position of the variation is given according to cDNA of the longest protein-coding transcript of the respective gene. [c]Variants present in all affected members of GLH5 were considered positive for disease co-segregation. [d]The novel/rare variations were checked in updated release of dbSNP and 1000 Genomes; and the variants present at minor allele frequency (MAF) ≤ 0.005 in the databases were included. The two new variants represented in bold segregated with JME in GLH5 and were found to be absent in 250 individuals of our control cohort.

quality score ≥20). The high quality processed sequencing reads were mapped to the human genome reference sequence (hg19/GRCh37) using BWA (v0.6.0). The sequence reads covered about 96% of the SureSelect probe region in the whole-exome (51.5 Mb) with mean coverage read depth of 66 (Table 3.3). On average, 90% and 76% of the whole-exome probe region was covered by at least 5 and 20 reads, respectively. As the disease-linked haplotype (EJM4) on chromosome 5 maps to 5q12-q14, we focused our analysis exclusively on this 25 Mb critical region. The SureSelect probes cover about 370 kb of exome region in this 25 Mb interval, of which 98% was covered with sequenced reads (91% coverage at 20x read depth) (Table 3.3).

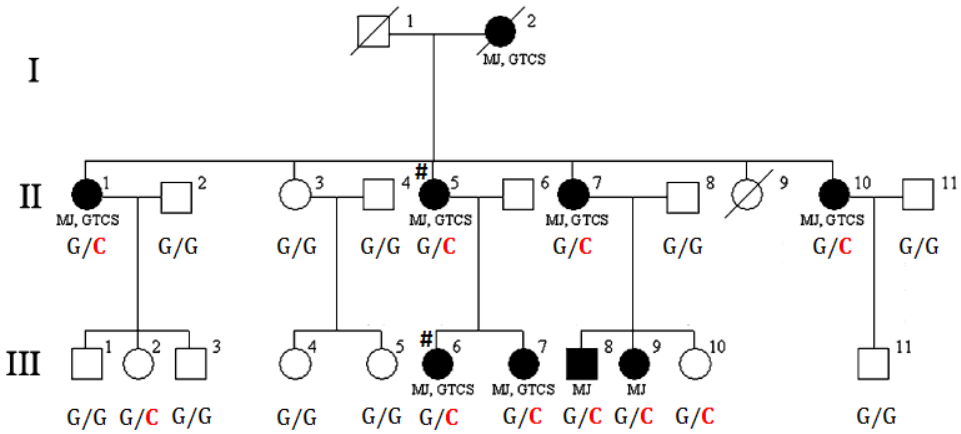

Figure 3.3: Segregation analysis of *TMEM171*, c.476G>C in GLH5: Pedigree of the three-generation GLH5 showing the segregation of c.476G>C mutation in *TMEM171* in all the affected members of the family. The mutation was found to be present in two unaffected individuals (III:2 and III:10) of the family. #Next-generation sequenced individuals (II:5 and III:6).

Small nucleotide variations (SNV) and indels (small insertions and deletions) were called from the aligned reads using Pileup utility of SAMTOOLS. Variants in the coding exons ± 100 bp of intronic sequence of all protein-coding genes in the 5q12-q14 region were only considered for analysis. Assuming autosomal mode of inheritance of JME in GLH5, 13 novel/rare heterozygous variations were identified (Table 3.4). These novel/rare variants were either absent or present at minor

The dot and comma represent the matched reference allele and alphabet shows the variant allele. **B.** Electropherograms of sequence with wild-type (G/G) and variant allele (G/C) for the c.476G>C variation. The arrow indicates the nucleotide showing heterozygous variation shown by presence of two peaks. **C.** Multi-species protein sequence alignment of TMEM171 by Clustal Omega. The glycine (G) 159 is highlighted in blue.

allele frequency (MAF) ≤ 0.005 in the public databases. Out of 13 novel/rare variants, only two were found to co-segregate with epilepsy in the family. These are: an intronic variant c.1873-22A>G in *COL4A3BP* (MIM: 604677) and a nonsynonymous variant c.476G>C (p.Gly159Ala) in *TMEM171* (Figure 3.3, Figure 3.4). Both variations were found absent in 250 individuals of control cohort. The common variants or polymorphisms identified in the region are enlisted in Appendix II A3.1.

3.3.2 Bioinformatics and minigene splicing analysis of the COL4A3BP variant

The c.1873-22A>G variation in *COL4A3BP* is present 22 bases upstream of its exon 16, in the intronic region of exon 15 and 16. According to the predictive bioinformatics tools, the variation forms an additional splice acceptor site upstream of exon 16, but with a score lower than wild-type splice site [BDGP: 0.93 (WT) and 0.54 (MT); NetGene2: 0.48 (WT) and 0.14 (MT)]. This predictive effect may lead to incorporation of 21 bases between the exons 15 and 16 due to aberrant splicing. The effect of the c.1873-22A>G variant on the normal splicing process of exon 15 and 16 was examined by constructing a minigene (Figure 3.5). The minigene consisted of ~2.7 kb insert comprising of exons 15 and 16 and their intervening intron, cloned into a mammalian expression vector pcDNA3.1 (+). In wild-type minigene (WT), the c.1873-22 position had 'A', whereas, the variant harboring minigene (MT) had 'G' at c.1873-22 nucleotide position. This minigene utilized the promoter sequence, transcription start and end signals of the vector pcDNA3.1 (+) and the splicing of the two exons was carried out by cellular splicing machinery. Wild-type and variant carrying minigene were transfected into HEK293T and COS-7 cells and cDNA was synthesized from their isolated total RNA. RT-PCR analysis identified the 309 bp spliced product from the wild-type and mutant minigene (Figure 3.6c). Sequencing of both amplified spliced products (exon 15 + exon 16) revealed no additional 21 bases due to the predicted additional splice acceptor site in the mutant minigene. This suggests that the intronic variation c.1873-22A>G neither affects the normal splicing of its flanking exons (15 and 16) in *COL4A3BP* nor forms any alternate transcript with additional

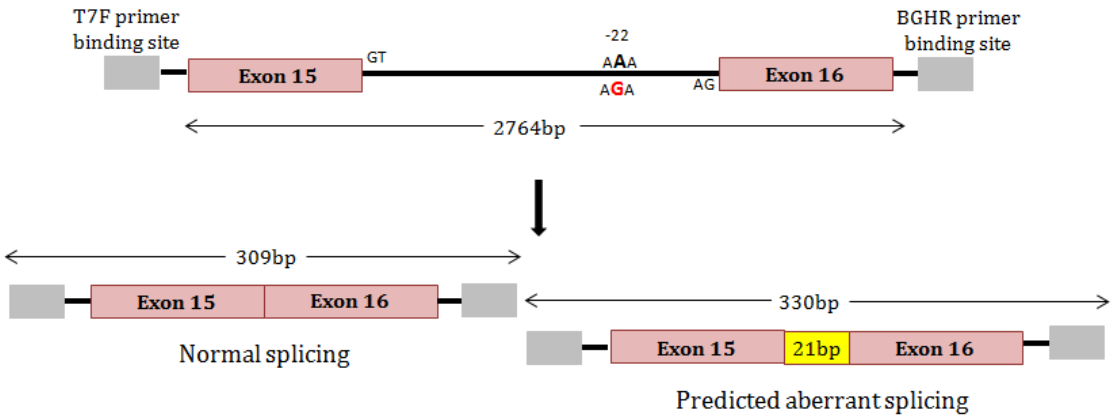

Figure 3.5: Schematic of *COL4A3BP* minigene construct: It represents normal splicing process of exons 15 and 16 of *COL4A3BP* and the predicted alternate splicing due to c.1873-22A>G variation upstream of exon 16. The normal spliced product of the minigene (from T7F to BGHR primer binding sites) is 309 bp, whereas if the variation leads to formation of additional splice acceptor site, the resulting product would have 21 bp inserted between exons 15 and 16 (330 bp).

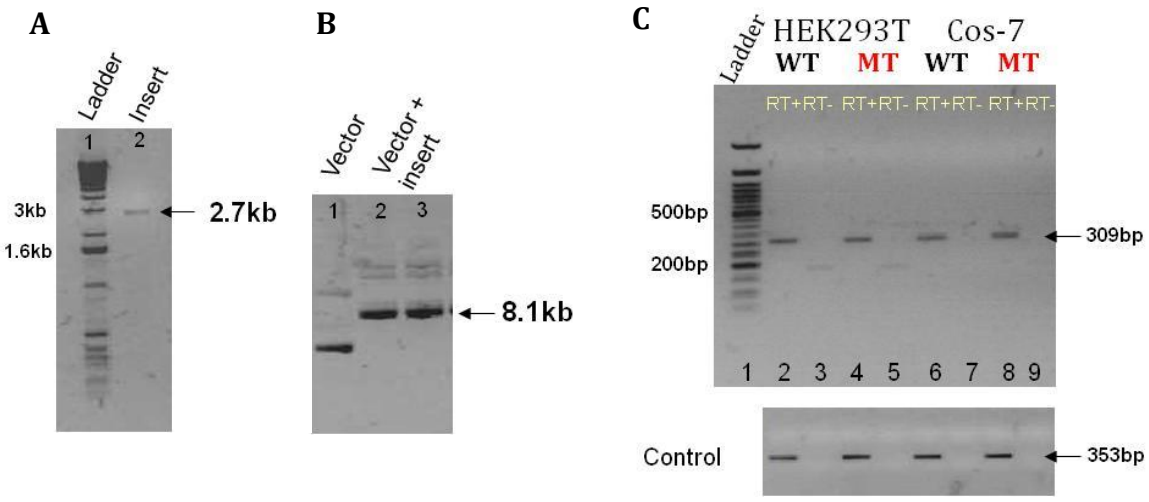

Figure 3.6: Minigene splicing analysis of *COL4A3BP* variant, c.1873-22A>G: **A**. The 2764 bp minigene consisting of exons 15 and 16 of *COL4A3BP* and their intervening intron was amplified from the genomic DNA of an affected individual of GLH5 family. The first lane is 1 kb ladder (Gibco) and in the second lane arrow indicates the ~2.7 kb amplified insert. **B.** Lane 1 shows the band for the pcDNA3.1(+) vector, and bands in lanes 2 and 3 represent the 8.1 kb constructs of minigene cloned in pcDNA3.1(+). **C.** The RT-PCR analysis of cDNA from wild-type (WT) and mutant/variant-harboring (MT) minigene transfected cells indicate presence of the wild-type spliced product of exons 15 and 16 (309 bp) in both. The arrows indicate the 309 bp spliced product of *COL4A3BP* minigene (upper panel) and the 353 bp product of human β-actin gene (control, lower panel). The lanes marked RT+ (2, 4, 6, 8) and RT- (control) (3, 5, 7, 9) indicate the reactions performed in presence and absence of SuperScript™ III reverse transcriptase. Lane 1 shows the 50 bp ladder (NEB).

21 base pairs. It indicates this allele to be apparently neutral and is not the disease-causing variant in GLH5.

3.3.3 Bioinformatics analysis of the TMEM171 variant

The heterozygous c.476G>C variant in *TMEM171* leads to alteration of glycine at 159 amino acid position to alanine (NP_775761.4). Multiple-species protein sequence alignment by Clustal Omega shows glycine at 159 amino acid position to be evolutionary highly conserved, indicating its functional importance (Figure 3.4c). The effect of p.Gly159Ala substitution in TMEM171 was predicted to be damaging by SIFT (score: 0.03) and probably damaging by Polyphen-2 (score: 0.988). SNAP and Pmut analysis predicted the effect of p.Gly159Ala to be non-neutral and pathological, respectively with a high reliability score. Align-GVGD classifies this missense mutation in Class C55, indicative of its high likelihood for interference in the protein function.

3.3.4 Mutational analysis of TMEM171

Sequence analysis of the coding exons and the flanking intronic region of *TMEM171* in JME patients revealed 12 novel/rare variants (Table 3.5). Of these, three variants c.269A>G (p.Gln90Arg), c.466C>T (p.Arg156Trp) and c.709G>A (p.Ala237Thr) result in uncommon missense mutations. The heterozygous variant alleles c.269A>G and c.466C>T were found to be either absent or present at minor allele frequency (MAF) less than 0.005 in the control cohort of 240 individuals and in dbSNP and 1000 Genomes databases. Due to the presence of c.709G>A as a homozygous variation in a control individual, it was not considered for further analysis. Apart from the p.Gly159Ala mutation in TMEM171 identified in GLH5 (Figure 3.4), two additional JME-associated mutations are: p.Gln90Arg and p.Arg156Trp (Figure 3.7). The p.Gln90Arg mutation was found in two unrelated JME patients (Table 3.6). Besides these, a few common variations were also detected in this screen (Appendix II A3.4).

***TMEM171* mutation**	**Gender**	**Age of onset (years)**	**Seizure types**	**EEG**	**Medication**
p.Gln90Arg	Female	15	MJ, ABS, GTCS	Normal	VPA
p.Gln90Arg	Female	11	MJ, GTCS	Gen SW	VPA
p.Arg156Trp	Female	NA	MJ	NA	VPA

MJ: myoclonic jerks, GTCS: generalized tonic-clonic seizures, ABS: absence seizures, Gen SW: generalized spike wave, VPA: Valporic acid, NA: Not available.

3.3.5 Bioinformatics analysis

According to information given in databases, human *TMEM171* gene is located at 5q13.2 and comprises three coding and one non-coding exon. It produces two alternate transcripts (NM_173490.7 and NM_001161342.2) encoding proteins of 324 (NP_775761.4) and 323 (NP_001154814.1) amino acids, respectively. The bioinformatics tools, TMHMM and PRED-TMR suggest that TMEM171 protein has four transmembrane domains (Figure 3.8). Information from LOCTREE3 and GeneCards (COMPARTMENTS) reveals that TMEM171 is likely to be a multi-pass membrane protein localizing to plasma membrane of the cell. The blastp algorithm of NCBI shows TMEM171 to be highly conserved protein across various organisms. Human TMEM171 shares more than 90% similarity with its orthologs in primates and ~60-80% in other mammals, with its proline-rich regions being the most conserved.

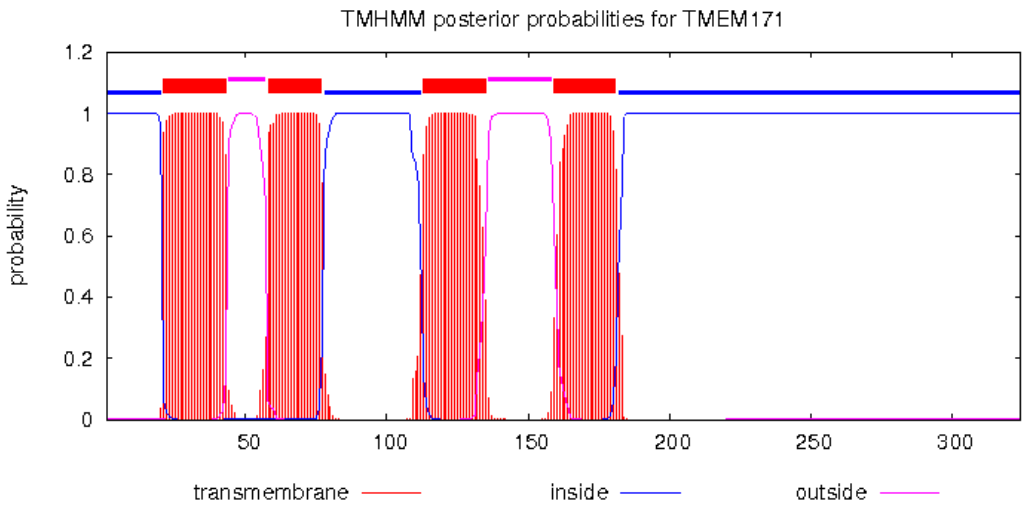

Figure 3.8: TMHMM2.0 prediction of TMEM171 transmembrane domains: The four predicted transmembrane domains of TMEM171 by TMHMM2.0. The probable amino acid positions of four transmembrane helices are 21-43, 58-77, 113-135, and 159-181.

The bioinformatics tools, SIFT, Polyphen-2 and Align-GVGD predict the functional effect of amino acid substitutions in a protein based on the protein sequence homology and biophysical properties of the amino acids. The mutation, p.Gly159Ala identified in GLH5 was predicted to be of damaging nature by these *in silico* tools. SIFT and Polyphen-2 predicts p.Gln90Arg as a benign mutation and p.Arg156Trp to be of damaging nature. Align-GVGD classifies p.Gln90Arg in class C35 indicating that it may affect the protein function and p.Arg156Trp, in class C65 suggesting that it is most likely to interfere with the protein function. The multi-species protein sequence alignment of TMEM171 by Clustal Omega showed glycine at 159 amino acid position to be evolutionary conserved (Figure 3.4c); and p.Gln90 and p.Arg156 to be moderately conserved across various organisms (Figure 3.7b).

3.3.6 Expression of TMEM171 in human brain regions

RT-PCR analysis was performed to detect the expression of *TMEM171* in human brain sub-regions, using Marathon-Ready™ cDNAs (Clontech) from hippocampus, cerebral cortex, hypothalamus and cerebellum. The intron-spanning primer pair specific to *TMEM171* yielded a 400 bp PCR product from the brain sub-regions analyzed and in the positive control [*TMEM171* pcDNA3.1 (+)] (Figure 3.9a). The forward primer was present in first coding exon and reverse primer was in the second coding exon of the gene. Sequencing of the amplified product revealed complete match with the nucleotide sequence of the *TMEM171* transcript (NM_173490.7, CCDS4017.1) in the region spanned by the primers. The amplified product from cDNA of hippocampus, cerebral cortex, hypothalamus and cerebellum indicates the expression of *TMEM171* at the transcript level in these human brain regions.

The expression profile of TMEM171 in various tissues was observed in the online database of GeneCards. According to the RNA expression studies, moderate levels of *TMEM171* expression was observed in brain regions (Figure 3.9b).

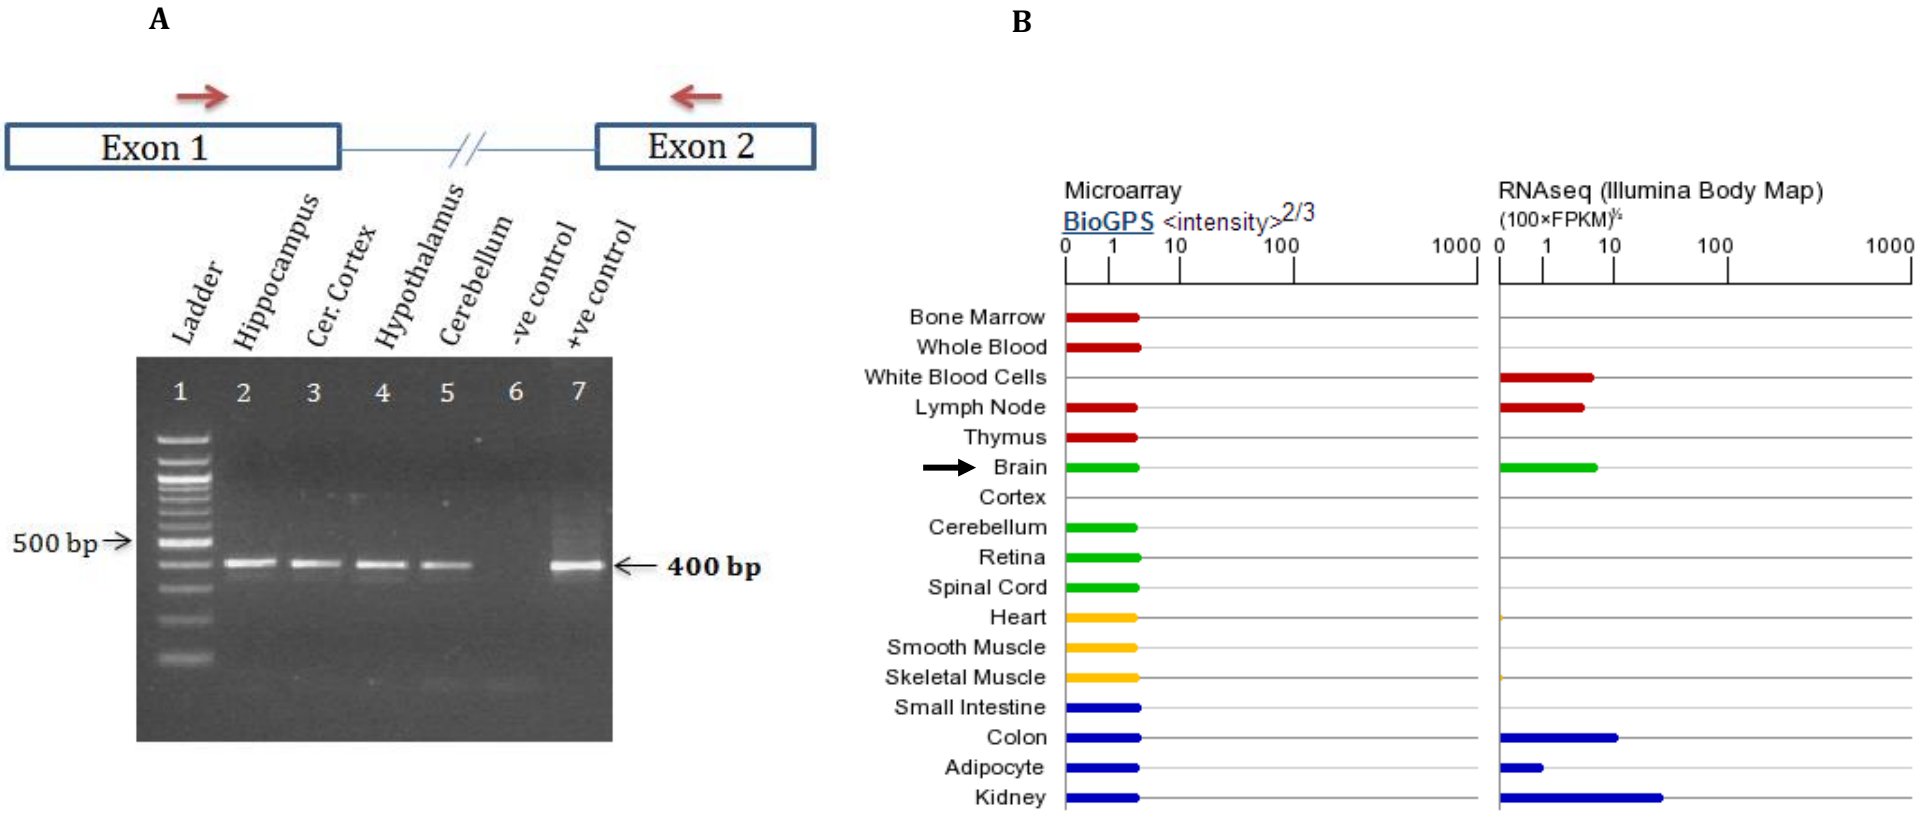

Figure 3.9: Expression of *TMEM171* in the human brain regions: A. RT-PCR analysis of cDNA from different brain regions (hippocampus, cerebral cortex, hypothalamus, and cerebellum). The arrow (lower panel) indicates the 400 bp product amplified by cDNA specific intron-spanning primers located in exon 1 and exon 2 (marked by arrows in upper panel) of *TMEM171*. Lane 6 shows the negative control (no DNA template) and lane 7 indicates the 400 bp product from the positive control [wild-type TMEM171 pcDNA3.1 (+) construct]. Lane 1 is the 100 bp ladder. **B.** Expression of *TMEM171* in various human tissues shown by the RNA expression data summarized in GeneCards. The arrow points to the normalized expression of *TMEM171* in human brain.

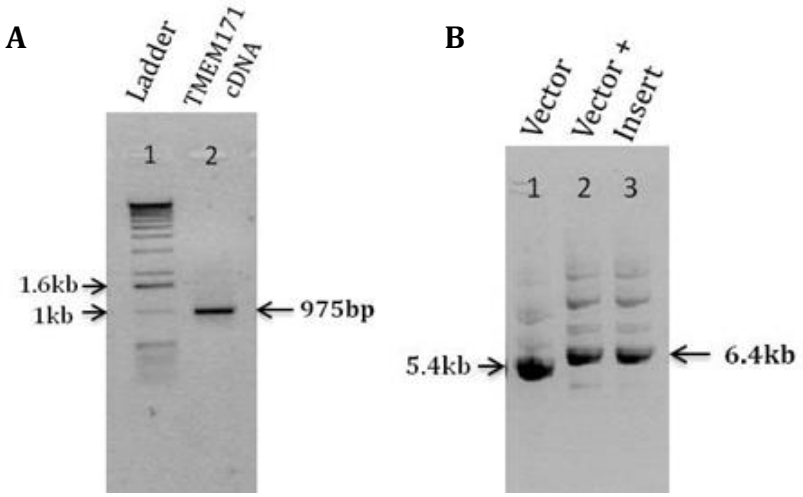

Figure 3.10: *TMEM171* cDNA cloning: A. The coding region of *TMEM171* transcript (NM_173490.7) amplified as a 975 bp product (indicated by arrow) from the TMEM171-AC-GFP (OriGene) construct. Lane 1 is the 1 kb ladder. **B.** The amplified *TMEM171* cDNA insert cloned in mammalian expression vector, pcDNA3.1 (+). Lane 1 indicate the 5.4 kb band of pcDNA3.1 (+), and lane 2 and 3 show the 6.4 kb constructs of wild-type TMEM171-pcDNA3.1 (+).

3.3.7 Cellular localization and expression of wild-type and mutant TMEM171 proteins

To examine the cellular localization of TMEM171 and to test whether the identified mutations (p.Gln90Arg, p.Arg156Trp, p.Gly159Ala) affect its localization, fluorescence immunocytochemistry was performed on HEK293T cells transiently transfected with the wild-type and mutant *TMEM171* pcDNA3.1 (+) constructs. Immunoreactivity was observed using mouse polyclonal anti-TMEM171 antibody (Sigma). TMEM171 protein expression was observed on the plasma membrane of the cell at non-permeabilized conditions and in the cytoplasm when cells were permeabilized (Figure 3.11). Though, the staining in permeabilized cells show TMEM171 expression in cytoplasmic region, its association to a particular sub-cellular organelle remains to be analyzed.

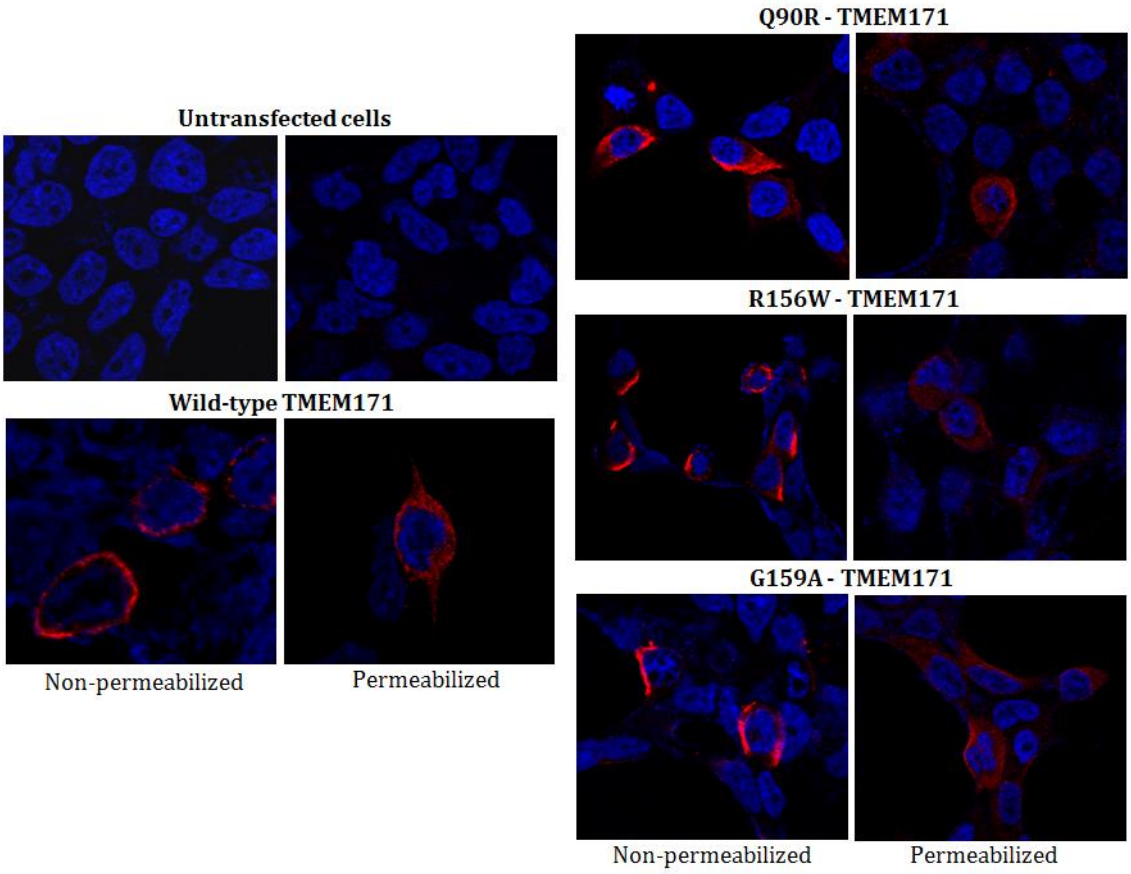

Figure 3.11: Cellular localization of WT and mutant (Q90R, R156W and G159A) TMEM171 proteins in transfected HEK293T cells: Fluorescence immunocytochemistry performed on HEK293T cells transiently transfected with wild-type and mutant (Gln90Arg, Arg156Trp, Gly159Ala) *TMEM171* cDNAs and the untransfected cells. Immunostaining was carried out at non-permeabilized and permeabilized conditions to observe cell surface and intracellular staining of TMEM171, respectively. Localization of TMEM171 was observed with mouse polyclonal anti-TMEM171 antibody (1 µg/µl, Sigma) and detected using Alexa Fluor® 568 goat anti-mouse IgG. The wild-type TMEM171 image shown here is obtained at 63x zoom. The untransfected HEK293T cells do not show any staining with the anti-TMEM171 antibody used.

The HEK293T cells transfected with mutant *TMEM171* constructs harboring mutations for p.Gln90Arg, p.Arg156Trp, p.Gly159Ala exhibited similar expression profile as seen for the wild-type protein at both non-permeabilized and permeabilized conditions (Figure 3.11). This suggests that these missense mutations do not seem to alter the plasma membrane localization of TMEM171. Untransfected HEK293T cells did not show any immunoreactivity with the anti-TMEM171 antibody used.

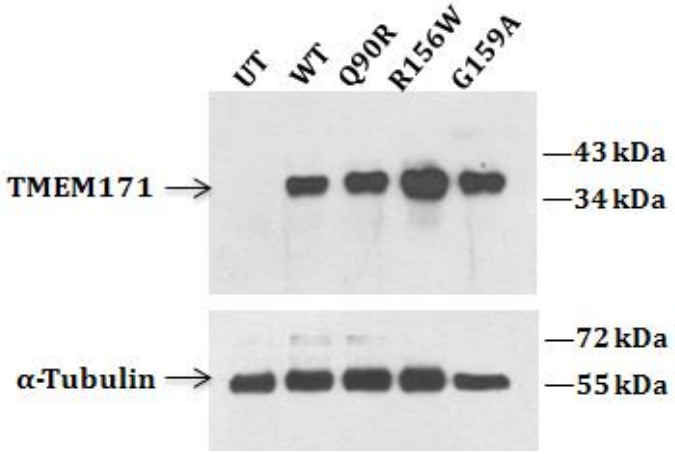

Figure 3.12: Expression of WT and mutant (Q90R, R156W and G159A) TMEM171 proteins in transfected HEK293T cells: Western blot analysis performed on lysates of HEK293T cells transiently transfected with wild-type (WT) and mutant (Gln90Arg, Arg156Trp, Gly159Ala) *TMEM171* pcDNA3.1 (+) and untransfected cells. Immunoreactivity for TMEM171 was observed with mouse polyclonal anti-TMEM171 antibody (1 µg/µl, Sigma). The α-Tubulin used here as a control was stained with the anti-α-Tubulin mouse monoclonal antibody. The HRP-conjugated rabbit anti-mouse IgG was used for detection for both, TMEM171 and α-Tubulin. The lysate from untransfected cells (UT) did not show any reactivity with the anti-TMEM171 antibody used.

Western blot analysis was conducted to examine the expression of TMEM171 in HEK293T cells transiently transfected with wild-type and mutant cDNAs, using a mouse polyclonal anti-TMEM171 antibody raised against the full-length human TMEM171 protein (Sigma, Cat. No. SAB1401999). The whole cell protein lysate from cells transfected with wild-type TMEM171 pcDNA3.1 (+) construct exhibits immunoreactivity with the antibody used, showing a specific band representing a protein of about 35 kDa (TMEM171 calculated mass: 34760 Da) (Figure 3.12). The protein from lysate of untransfected cells does not show any signal with this antibody. The mutant TMEM171 proteins with p.Gln90Arg, p.Arg156Trp or p.Gly159Ala, are observed to express at equivalent levels to that of the wild-type protein (Figure 3.12). Due to the over expression of the wild-type and mutant proteins in the transfected cells, quantifying small changes in the expression levels caused due to the mutations is not plausible.

The epilepsy-associated mutations in TMEM171, p.Gln90Arg, p.Arg156Trp and p.Gly159Ala, do not seem to alter the localization or expression levels of their respective mutant proteins in transiently transfected HEK293T cells.

3.4 Discussion

In this chapter, findings from the whole-exome sequencing experiment, to identify potentially causative genes at EJM4 are presented. The NGS analysis of exome dataset from two affected individuals of Family GLH5, led to identification of novel/rare variants in two genes, *COL4A3BP* and *TMEM171* at 5q12-q14 locus, which appeared suitable for further studies.

The intronic variant in *COL4A3BP* does not seem to affect the splicing and appears to be a rare benign change. But, the missense mutation in *TMEM171* substitutes an evolutionary conserved amino acid residue, glycine at position 159 to alanine; and is predicted to have deleterious effect on the protein structure and function. This heterozygous variant was found in all the affected individuals of GLH5 and was absent in our control cohort and public databases such as dbSNP and 1000 Genomes. However in 1000 Genomes database, a rare variation (MAF: 0.0008) leading to p.Gly159Glu in TMEM171 has been recorded. Due to rarity of this alteration and possibility of multiple mutations at same amino acid residue, the glycine to alanine change at 159 in TMEM171 was examined further. Thus, whole-exome sequencing analysis of the EJM4 locus (5q12-q14) facilitated the discovery of a novel mutation in a plausible epilepsy-causing gene, *TMEM171*.

TMEM171 encodes a 324 amino acid proline-rich transmembrane protein, also known as PRP2 (Proline rich protein 2). The biological structure and function of TMEM171 protein is not known so far. It is predicted to have four transmembrane domains (Figure 3.8) and localizes to the plasma membrane (Figure 3.11). According to available information in databases, *TMEM171* mRNA was detected in spleen, brain, spinal cord, fetal brain, kidney, liver etc (GeneCards) (Figure 3.9b). In nervous system, its mRNA expression is observed in prefrontal cortex, hypothalamus, amygdala, pons, medulla oblongata, dorsal root ganglion (RNA

expression data, GeneCards). As a primary step in examining the role of *TMEM171* in a brain disorder, we identified its expression at transcript level in cDNA library from different human brain sub-regions (Figure 3.9a). So far, no study has either characterized the biological function of TMEM171 or reported its role in any brain-related disorders. However, genome-wide association studies suggest that the genomic region nearby *TMEM171* may be associated with serum urate concentrations and kidney function-related traits (Köttgen et al 2013, Okada et al 2012).

Further, while exploring the role of *TMEM171* as an epilepsy-linked gene, we identified two additional JME-associated novel/rare mutations, p.Gln90Arg and p.Arg156Trp in our cohort of 480 JME patients. Taken together, the three mutations identified in this study alter conserved amino acid residues in TMEM171 and two of the three variations are predicted to have damaging effect on the protein function. Though these missense mutations do not seem to affect the membrane targeting or expression of the protein, it is suggested that they may have an effect on its biological function. We propose that these mutations may either perturb the interaction of TMEM171 with other proteins or may alter its structural-functional properties. We hypothesize based on few studies from the literature, such as mutations in *TBC1D24*, a protein with unknown function, impair its interaction with *ARF6* (regulates dendritic branching and neurite extension) and leads to neuronal hyperexcitability in familial infantile myoclonic epilepsy (Falace et al 2010). Interestingly, mutations in various proteins belonging to the group of uncharacterized transmembrane proteins have been implicated in neurological disorders, such as *PRRT2* gene which encodes for a proline-rich transmembrane domain protein 2 of an unknown function. Mutations in *PRRT2* have been identified for disease phenotypes such as paroxysmal kinesigenic dyskinesia (PKD), Paroxysmal kinesigenic dyskinesia with infantile convulsions (PKD/IC), Benign familial infantile epilepsy (BFIE) and infantile convulsions and choreoathetosis (ICCA) (Chen et al 2011, Lee et al 2012, Heron et al 2012). So far no homology has been found between TMEM171 and other reported TMEM molecules which we have analyzed. However, mutations in other TMEM proteins have also been identified such as in *TMEM216* and *TMEM237* for the Joubert

syndrome related disorders (Edvardson et al 2010, Valente et al 2010, Huang et al 2011); and in *TMEM240* for spinocerebellar ataxia with mental retardation and severe cognitive impairment (Delplanque et al 2014).

Therefore, based on the findings presented in this chapter, a suggestion is made for *TMEM171* as an underlying genetic cause for epilepsy in GLH5 at EJM4 (5q12-q14). We provide evidence at gene- and variant- level for its association to epilepsy (McArthur et al 2014). Gene-level evidence is based on the exclusion of all rare variants except p.Gly159Ala in *TMEM171* in the disease-linked region on chromosome 5, presence/absence in dbSNP and 1000 Genomes databases and control cohort from south India, conservation of the variant residue and predicted damaging functional impact. Two additional rare missense variants were found in three unrelated JME patients. Variant-level evidence is provided by their rare presence (M.A.F<0.005), evolutionary conservation of the altered residue and predictive functional pathogenicity. While the physiological function of *TMEM171* and its role in epilepsy mechanism needs further studies, identification of novel/rare epilepsy-linked mutations in *TMEM171* provides genetic evidence for its involvement in causation of GGE/JME.

[a]Genomic position of the nucleotide base on chromosome 3 (chr 3) (GRCh37 p.13, NCBI). [b]The position of amino acid is numbered according to one of the protein-coding transcripts for the gene (dbSNP 142, NCBI). Hom, homozygous; Het, Heterozygous

[a]Genomic position of the nucleotide base on chromosome 3 (chr 3) (GRCh37, NCBI). [b]The nucleotide and amino acid residue position of the variations in *CASR* is according its shorter transcript encoding for receptor of 1078 amino acids (NM_000388.3, NP_000379.2). [c]Minor allele frequencies (MAF) for the variation given in the dbSNP or 1000 genomes databases. [d]Minor allele frequencies (MAF) calculated in 252 individuals of control cohort.

Appendix II

A3.1 Known/common variations observed in exome sequencing data of individuals II:5 and III:6 (GLH5) in the 5q12-q14 region

[a]Genomic position of the nucleotide base on chromosome 5 (chr 5) (GRCh37 p.13, NCBI). [b]The position of amino acid is numbered according to one of the protein-coding transcripts for the gene (dbSNP 142, NCBI). Hom, homozygous; Het, Heterozygous

A3.2 Primer pairs used for amplification and sequencing

[a]Genomic position of the nucleotide base on chromosome 5 (chr5) (GRCh37, NCBI). [b]The nucleotide and amino acid residue position of the variations in *TMEM171* is according its longer transcript encoding for protein of 324 amino acids (NM_173490.7, NP_775761.4). [c]Minor allele frequencies (MAF) for the variation given in the dbSNP or 1000 genomes databases. [d]Minor allele frequencies (MAF) calculated in 240 individuals of control cohort.
